INDEX TO VOLUME CLVII.

AUTHORS.

Achorn, John W. Habit cure, mental and physical, 260.
Adams, John D. Report of a case of fracture into acetabulum, with separation at sacro-iliac synchondrosis without clinical symptoms, 432; strain as a causative factor in infectious arthritis, 859.
Adams, J. F. Alleyne. The segregation of consumptives. The annual discourse delivered before the Massachusetts Medical Society, June 12, 1907, 35.

Baker, Harold W., and Cunningham, John H., Jr. A soluble bobbin for intestinal anastomosis, 214.
Balch, F. G. Suprapubic prostatectomy and stone in bladder. Rupture of the intestine. Echinococcus cyst of liver, 825.
Barker, Lewellys F. On neurological and psychiatric diagnosis, 147.
Barney, J. Dellinger. Cancer of the male urethra. A report of two cases, 790.
Beebe, S. P. The results of the chemical investigation of tumors, 853.
Benson, Charles S. The prostate from the surgical standpoint, 519.
Blake, J. Bapst. Fractured skull with extensive defect of bone, 334; walking and health, 877.
Boothby, Walter M. The so-called "Ochsner muscle" of the duodenum, 80.
Bossidy, John C. The "optometrist." A warning word, 857.
Bottomley, John T. The operative treatment of varicose veins of the lower extremity, 351.
Bottomley, John T., and Leen, Thomas F. Tuberculous ulcer of the ileum. Perforation. General peritonitis. Operation. Death, 605.
Bowen, John T. Verrucæ plantares; their prevalence in boys and in young men, and their pathology, 781.
Bowen, John T., and Towle, Harvey P. Progress in dermatology, 561; report on dermatology, 531.
Bradford, E. H., and Sever, James W. Torticollis. The results of the treatment of cases of acquired and congenital muscular torticollis at the Boston Children's Hospital, since 1879, 241.
Bradford, E. H., and Soutter, Robert. Muscle and tendon transference, 655.
Brooks, W. A., and Paul, W. E. Report of a case of dissecting aneurism with rupture of the aorta; autopsy, 727.
Brown, Percy. Pulmonary tuberculosis and the Röntgen rays, 417.
Brown, Philip King. Letter from San Francisco. The plague situation in San Francisco, 717.
Bulkeley, Frank S. The serum treatment of exophthalmic goiter. A review of the literature, 626.
Burrage, Walter L. Progress in gynecology, 760.

Cabot, Arthur T. Modern operations for complete removal of the prostate, 456.
Cabot, Follen. Prostatectomy in two stages by special technic, 554, 653.
Cabot, Richard C. The historical development and relative value of laboratory and clinical methods of diagnosis, 150; the three long-continued fevers of New England, 281.
Cates, Benjamin B. An abdominal lesion simulating cancer, 663.
Chase, Richard F. Diagnosis of gastric cancer, 721.
Cheever, David. Diffuse peritonitis; drainage; intestinal paralysis, secondary enterostomy, with relief of symptoms, 335.
Christian, Henry A. A critical estimate of the fermentation specific gravity method of quantitating sugar in diabetic urine, 178; medical teaching at Harvard and the opportunity it offers the young graduate for medical training, 67; progress in the theory and practice of medicine, 222.
Chute, Arthur L. A suppurating supernumerary ureter opening into the prostatic urethra, 385.
Cobb, Farrar. A case of extensive resection of the stomach for carcinoma, 110; perforating typhoid ulcers, 78; a strange reason for persistent abdominal pain. Intestinal adhesions caused by a pin which had penetrated the umbilicus without the knowledge of the patient, 18; pseudo-tuberculosis of the peritoneum. Report of a case, 861.
Conlon, Frank A. Glottic spasm of nasal origin in adults, 186.
Coriat, Isador H. Nocturnal paralysis, 47; some further studies on nocturnal paralysis, 751.
Councilman, W. T. Some general considerations regarding tumors, 313.
Cowles, William N. Lead poisoning in a rural community, 325.
Craig, Daniel H. The utero-sacral ligaments, 101.
Creeley, Oscar S., and Stetson, Frank E. A case of non-ulcerative follicular ileocolitis, 759.
Crockett, E. A. Two cases of hemorrhage following the removal of the tonsils, 661.
Cumston, Charles G. A case of suprapubic cystostomy on a prostatic; with remarks on the technic and indications of this operation, 788; the question of "justifiable homicide," 429, 464, 495, 529, 556.
Cunningham, John H., Jr. Rectal anesthesia, 355.
Cunningham, John H., Jr., and Baker, Harold W. A soluble bobbin for intestinal anastomosis, 214.
Cyriax, Edgar F. Henrik Kellgren and his methods of manual treatment, 490.

DeBlois, T. A. Lipoma of the epiglottis, 327.
Dewis, John W. Comparative tests for occult blood in gastric contents and feces, with especial reference to the benzedin test, 169.
Doolittle, W. F. Congenital dexiocardia, 663.
Drew, C. A. The treatment of fever cases in the public service, 181.
Dunn, Charles H. Recent advances in the knowledge of tuberculosis in early life, 389.

Emerson, F. P. General lympho-sarcoma accentuated in the pharynx, 397.
Emmons, Arthur B., 2d, and Rhea, Lawrence J. A series of ninety-one consecutive blood cultures, 809.

Finney, J. M. T., and Friedenwald, Julius. The report of an unusual case of ulcer of the stomach, 393.
Fisk, Samuel A. A search for a suitable climate, 252.
Floyd, Cleaveland, and Stone, Arthur K. The daily care of consumptives at a general hospital as an aid to solving local tuberculosis problems, 141.
Fremont-Smith, F. The effect of Florida climate upon acute and chronic disease, 813.
Friedenwald, Julius, and Finney, J. M. T. The report of an unusual case of ulcer of the stomach, 393.

Gould, George M. The origin of right-handedness, 597.
Graves, W. P. Retroversion and its treatment; an analysis of five hundred consecutive cases at the Free Hospital for Women, 1.
Green, C. M. A case of obstetrical paralysis in a baby eight days old. Post-diphtheritic intestinal paresis, 329; two cases of intra-ligamentous fibro-myoma of the uterus, and the method employed to control bleeding from the bed of the tumor in the broad ligament, 295.
Greenwood, Allen. Ocular injuries from dynamite explosions. Sympathetic ophthalmia. Conjunctival graft for corneal ulcer, 329.
Gulick, Luther H. A department of school hygiene, 113.

Hall, William D., and Standish, Myles. Recent progress in ophthalmology, 498.
Harrington, Charles. Medical inspectors: their function, 291.
Harte, Richard H. The medical and surgical aspects of perforating typhoid ulcers, 69.
Hartwell, H. F., and Lee, Roger I. The treatment of simple infections of the staphylococcus aureus with the "vaccines of Wright," 523.
Heffenger, A. C. Some personal experiences in abdominal surgery, 526.
Hill, T. Chittenden. The technic to be observed in the examination and local treatment of the upper rectum and pelvic colon, 747.
Hoag, Louis. "Organism X," probably of the coryne-bacterium group; its differentiation from B. diphtheriæ and allied organisms. Its pathogenicity in man, especially in bronchopneumonia and its relation to general paralysis of the insane, 10.
Hubbard, Joshua C. Arterio-venous anastomosis, 185.

Illoway, H. The reaction of some milk modifications to rennet, 462.

Jack, Frederick L., and Verhoeff, Frederick H. "A case of chronic otitis media, hemorrhage into the external auditory canal, perforation of the wall of pharynx, with fatal hemorrhage from the jugular vein, 17.
Jones, D. F. Echinococcus cyst of the liver and of the gall bladder, 826.
Joslin, Elliott P. Acidosis, 40.
Joslin, Elliott P., and Overlander, Charles L. Separate nursing and isolation in typhoid fever, 427.

Kittredge, F. E. Two cases of brain abscess, 396.
Knapp, Philip C. Heredity in diseases of the nervous system with especial reference to heredity in epilepsy, 485; Professor Mendel's greatest service to neurology, 167.
Knopf, S. A. An appeal to the American medical profession, 203.
Knowlton, John G. W. Tarsal injuries, 636.

Larrabee, Ralph C. Vicarious menstruation with a report of two cases, 217.
Lee, Roger I., and Hartwell, H. F. The treatment of simple infections of the staphylococcus aureus with the "vaccines of Wright," 523.
Leen, Thomas F., and Bottomley, John T. Tuberculous ulcer of the ileum. Perforation. General peritonitis. Operation. Death, 605.
Lothrop, Howard A. Case of anthrax or malignant pustule. Typhoid fever, with acute cholecystitis and perforation of gall bladder. Foreign body in knee, 334; neuralgia of the superior maxillary nerve, 8.
Lund, F. B. A case of multiple operations for abdominal adhesions, 295; a case of perforation of the intestine in typhoid fever. Operation. Recovery, 330.
Lund, F. B., and White, Franklin W. Case of benign indurated ulcer of the pylorus simulating malignancy of operation. Excision of the pylorus. Division and re-supplantation of common bile duct. Recovery. Case of pyloric obstruction due to ulcer scar and adhesions. Posterior gastro-enterostomy. Recovery, 330.

Marcy, Henry O. Davis memorial fund, 33.
Mays, Thomas J. Immunity and therapeutic action, 695.
Miller, Albert H. The seashore treatment of the tubercular arthritis of children, 659.

Morrison, H. A study of fifty-one cases of debility in Jewish patients from the Massachusetts General Hospital, 816.
Morse, John L., and Rotch, Thomas Morgan. Progress in pediatrics, 19.
Mumford, J. G. Progress in surgery, 638, 664.

Ogden, J. Bergen. Progress in physiological chemistry, 114.
O'Neil, Richard F. Some remarks on nephrolithiasis, 44.
Otis, Edward O. The blood pressure as a guide in the treatment of hemoptysis, 211; the early diagnosis of pulmonary tuberculosis for the general practitioner, 361.
Overlander, Charles L., and Joslin, Elliott P. Separate nursing and isolation in typhoid fever, 427.

Painter, Charles F. Experience with opsonins and bacterial vaccines in the treatment of tuberculous and nontuberculous arthritis, 621.
Paul, Luther G. A study of seven hundred and fifty fractures of long bones of the lower extremity, with special reference to the cause of delayed union, 255.
Paul, W. E., and Brooks, W. A. Report of a case of dissecting aneurism with rupture of the aorta; autopsy, 727.
Porter, C. A. Two cases of excision of adeno-carcinoma of the rectum, with preservation of sphincter. Cancer of prostate. Complete prostatectomy by Loring's method. Diverticulum of bladder. Extra-peritoneal removal with suture, 819.
Pratt, Joseph H. The organization of tuberculosis classes, 285.
Prince, Morton. The treatment of typhoid fever by special sera and statistical methods of research, 685.
Prouty, Ira J. The dignity of medicine, 277.

Quinby, William C. Hemorrhagic infarct of the intestine, 383.

Reynolds, Edward. The superiority of primary over secondary Cesarian sections, and the feasibility and advantages of a predetermination of the method of delivery, 581.
Rhea, Lawrence J., and Emmons, Arthur B., 2d. A series of ninety-one consecutive blood cultures, 809.
Richardson, Mark W. On the treatment of typhoid fever with specific sera, filtrates and residues (Vaughan), 717; treatment of typhoid fever with specific sera, filtrates and residues (Vaughan), 449.
Richardson, Oscar, Vickery, H. F., and Wright, J. H. Malignant disease of pleura, with exhibition of specimen, 824.
Roberts, Dudley. Underfeeding and its associated ills, 692.
Robinson, Beverley. "The early diagnosis of pulmonary tuberculosis for the general practitioner," 415.
Robinson, Byron. Anatomic and physiologic rest of the peritoneum in peritonitis, 634.
Rogers, Alfred P. The correction of malocclusion and its relation to rhinology, 784.
Rollins, William. Notes on x-light. Note, 203. On the use of fused silica in vacuum tubes, 779.
Rotch, Thomas M. The Roentgen ray in pediatrics, 547.
Rotch, Thomas M., and Morse, John L. Progress in pediatrics, 19.

Schaefer, Theodore W. The contamination of the air of our cities with sulphur dioxid, the cause of respiratory disease, 106.
Scudder, Charles L. Mistaken diagnosis in cases of typhoid perforation, 76; stenosis of the pylorus in infancy, 321.
Sever, James W., and Bradford, E. H. Torticollis. The results of the treatment of cases of acquired and congenital muscular torticollis at the Boston Children's Hospital, since 1879, 241.
Shattuck, Frederick C. The past, present and future of tuberculosis, 133; perforating typhoid ulcers, 75; the science and art of medicine in some of their aspects, 63.
Shattuck, George C. Letter from China. Climate and diseases in Shanghai and Canton. Medical practice, 95.
Shaw, Arthur J. Warm air for inflation of the ear, 578.
Smith, George C. The psychic factor in disease, 205.
Smith, Theobald. The channels of infection in tuberculosis, together with some remarks on the outlook concerning a specific therapy, 420.
Smith, R. M., and Taylor, E. W. A simple method of reconstructing nerve plexuses, 700.
Soutter, Robert. A brace for postural curvature of the spine, 726; a portable traction and retentive apparatus for use in fracture of and operations on the lower extremity, 724.
Soutter, Robert, and Bradford, E. H. Muscle and tendon transference, 655.
Standish, Myles, and Hall, William D. Recent progress in ophthalmology, 498.
Stedman, Henry R. Report on mental disease, 764; the need of popular lectures on insanity, 483.
Stetson, Frank E., and Creeley, Oscar S. A case of non-ulcerative follicular ileocolitis, 759.
Stone, Arthur K. A case of intestinal tuberculosis with psychoneurotic symptoms, 560; tuberculosis at the Long Island Hospital, 511.
Stone, Arthur K., and Floyd, Cleaveland. The daily care of consumptives at a general hospital as an aid to solving local tuberculosis problems, 141.
Swasey, Edward. Exophthalmic goiter, 754.
Swift, Henry M. Delirium and delirious states, 687.
Sylvester, Charles P. Hydrophobia and its prevention, 97.

Taylor, E. W. Medical expert testimony, 601; senile trepidant abasia, 220; painless labor. Report of a case due to a destructive lesion of the spinal cord, 14; the attitude of the medical profession toward the psycho-therapeutic movement, 843.
Taylor, E. W., and Smith, R. M. A simple method of reconstructing nerve plexuses, 700.
Torbert, James R. Dystocia due to fibroids. Intra-uterine death of fetus. Craniotomy, 729.
Towle, Harvey P. Dermatitis herpetiformis (herpes gestationes). Raynaud's disease, 825.
Towle, Harvey P., and Bowen, John T. Progress in dermatology, 561; report on dermatology, 531.
Tracy, Edward A. Acute inflammation of tendon sheaths sequential to acute tonsillitis, 114.

Verhoeff, Frederick H., and Jack, Frederick L. "A case of chronic otitis media, hemorrhage into the external auditory canal, perforation of the wall of pharynx, with fatal hemorrhage from the jugular vein, 17.
Vickery, H. F. A case of Stokes-Adams disease with exhibition of the patient, 823.
Vickery, H. F., Richardson, Oscar, and Wright, J. H. Malignant disease of pleura, with exhibition of specimen, 824.

Walton, G. L. Anterior poliomyelitis in the adult, with illustrative cases, 719.
Watson, Francis S. Twenty-five years' experience in the treatment of stricture of the urethra, 549.
Webster, F. P. Diagnosis and treatment of diphtheria in young children, 698.
Wellman, F. Creighton. Report of a peculiar disease of tropical Africa called "onyalai," 365.
Wheatley, Frank G. Factory inspection, 293.
White, Franklin W. Cancer of colon, 296; case of neurosis of esophagus, 333; gastric ulcer, 296.
White, James C. The president's address to the Sixth International Dermatological Congress held in New York, Sept. 9–14, 1907, 512.
White, Franklin W., and Lund, F. B. Case of benign indurated ulcer of the pylorus simulating malignancy of operation. Excision of the pylorus. Division and re-supplantation of common bile duct. Recovery. Case of pyloric obstruction due to ulcer scar and adhesions. Posterior gastro-enterostomy. Recovery, 330.

SUBJECTS.

Abasia. Senile trepidant abasia. Report of cases, Taylor, E. W., 220.

Abdomen. An abdominal lesion simulating cancer, Cates, Benjamin B., 663; a strange reason for persistant abdominal pain. Intestinal adhesions caused by a pin which had penetrated the umbilicus without the knowledge of the patient, Cobb, Farrar, 18; some personal experiences in abdominal surgery, Heffenger, A. C., 526; a case of multiple operations for abdominal adhesions, Lund, F. B., 295.

Abscess. Two cases of brain abscess, Kittredge, F. E., 396.

Acidosis. Acidosis, Joslin, Elliott P., 40.

Addresses. The segregation of consumptives. The annual discourse delivered before the Massachusetts Medical Society, June 12, 1907, Adams, J. F. Alleyne, 35; pulmonary tuberculosis and the Roentgen rays, Brown, Percy, 417; medical teaching at Harvard and the opportunity it offers for the young graduate for medical training, Christian, Henry A., 67; some general considerations regarding tumors, Councilman, W. T., 313; the dignity of medicine, Prouty, Ira J., 277; the past, present and future of tuberculosis, Shattuck, Frederick C., 133; the science and art of medicine in some of their aspects, Shattuck, Frederick C., 63; the psychic factor in disease, Smith, George Carroll, 205; the president's address to the Sixth International Dermatological Congress held in New York, Sept. 9–14, 1907, White, James C., 513.

Anastomosis. A soluble bobbin for intestinal anastomosis, Cunningham, John H., Jr., and Baker, Harold W., 214; arterio-venous anastomosis, Hubbard, Joshua C., 185.

Anemia. Profound anemia and purpura, Withington, Charles F., 328.

Aneurism. Report of a case of dissecting aneurism with rupture of the aorta; autopsy, Paul, W. E., and Brooks, W. A., 727; aneurism of both carotids, Withington, Charles F., 328; a case of slow-growing aneurism of the aortic arch, Withington, Charles F., 328.

Anthrax. Case of anthrax or malignant pustule, Lothrop, H. A., 334.

Arthritis. The seashore treatment of the tubercular arthritis of children, Miller, Albert H., 659; experience with opsonins and bacterial vaccines in the treatment of tuberculous and nontuberculous arthritis, Painter, Charles, F. 621; strain as a causative factor in infectious arthritis, Adams, John D., 859.

Bladder. Suprapubic prostatectomy and stone in bladder, Balch, F. G., 825; diverticulum of bladder. Extra-peritoneal removal with suture, Porter, C. A., 819.

Blood. Comparative tests for occult blood in gastric contents and feces, with especial reference to the benzedin test, Dewis, John W., 169; the blood pressure as a guide in the treatment of hemoptysis, Otis, Edward O., 211; a series of ninety-one consecutive blood cultures, Rhea, Lawrence J., and Emmons, Arthur B., 2d, 809.

Books Reviewed. Anders, Howard S., physical diagnosis, with case examples of the inductive method, 831; Ardin-Delteil, P., et Soubeyran, P., petite chirurgie et pratiques spéciales courantes, 868; Ashton, William Easterly, a textbook on the practice of gynecology, 85; Bashore, Harvey B., outlines of practical sanitation, 372; Beck, Carl, surgical diseases of the chest, 301; Billings, Frank, editor, modern clinical medicine. Diseases of the digestive system, 121; Binnie, John Fairbairn, manual of operative surgery, 159; Bland-Sutton, J., gallstones and diseases of the bile ducts, 530; Brickner, Walter M., and Moschcowitz, Eli, five hundred suggestions, practical brevities in surgical diagnosis and treatment, 831; Brown, J. J. Graham, and Ritchie, W. T., medical diagnosis, 193; Bryant, Joseph D., and Buck, Albert H., editors, American practice of surgery, 501; Buchanan, A.M., manual of anatomy, systemic and practical, including embryology, 437; Calot, F., treatment of caries of the spine. Treatment of congenital dislocation of the hip, 501; Campbell, Harry, on treatment, 403; Cripps, Harrison, cancer of the rectum, its surgical treatment, 536; Da Costa, John Chalmers, modern surgery, general and operative, 644; De Lee, Joseph B., obstetrics for nurses, 121; Durland, W. A. Newman, the American illustrated dictionary, third edition, 85; fourth edition, 373; Drew, Gilman A., a laboratory manual of invertebrate zoölogy, 644; Edwards, Arthur R., a treatise on the principles and practice of medicine, 568; Eisendrath, Daniel N., a textbook of clinical anatomy, 707; surgical diagnosis, 266; Emerson, Charles Phillips, clinical diagnosis, 340; Fleming, Robert A., a short practice of medicine, 768; Forchheimer, F., the prophylaxis and treatment of internal diseases, 535; Fowler, George Ryerson, a treatise on surgery, 404; Fowler, Russell S., the operating room and the patient, 868; Friedenwald, Julius, and Ruhrah, John, diet in health and disease, 300; Gleason, E. B., a manual of diseases of the nose, throat and ear, 706; Gottheil, W. S., treatment of skin cancers, 159; Gould, Alfred H., the technic of operations upon the intestines and stomach, 267; Green, William & Sons, Green's encyclopedia and dictionary of medicine, Vols. III and IV, 230; Vol. V, 404; Greene, Robert Holmes, and Brooks, Harlow, diseases of the genito-urinary organs and the kidney, 708; Griffith, J. P. Crozer, the care of the baby, 536; Halliburton, W. D., essential of chemical physiology, 500; Hare, Hobart Amory, a textbook of the practice of medicine, 737; a textbook of practical therapeutics, with especial reference to the application of remedial measures to disease and their employment upon a rational basis, 644; Hawk, Philip B., practical physiological chemistry, 768; Head, Gustavus P., editor, the practical medicine series, 301; Hecker, R., and Trumpp, J., atlas and epitome of diseases of children, 121; Heisler, John Clement, a textbook of embryology for students of medicine 736; Herman, George Ernest, diseases of women, 193; Hirschell, George, indigestion, 159; Hirst, Barton Cook, a textbook of obstetrics, 121; Jackson, Chevalier, tracheo-bronchoscopy, esophagoscopy and gastroscopy, 736; Jewett, Charles, editor, the practice of obstetrics by American authors, 472; Keen, William Williams, editor, surgery: its principles and practice, 797; Kerr, Le Grand, diagnostics of diseases of children, 121; King, A. F. A., manual of obstetrics, 707; Kitt, Th., textbook of comparative general pathology, 372; Kyle, John Johnson, manual of diseases of the ear, nose and throat, 736; Lewis, Frederic T., Stöhr's histology arranged upon an embryological basis, 121; Lindsay, James Alexander, lectures on diseases of the lungs, 736; Lloyd, William, hay-fever, hay-asthma, its causes, diagnosis and treatment, 735; Lovett, Robert W., lateral curvature of the spine and round shoulders, 501; Meige, Henry, and Feindel, E., tics and their treatment, 373; Mendel, E., textbook on psychiatry, 230; Milne, John Stewart, surgical instruments in Greek and Roman times, 435; Montgomery, E. E., practical gynecology, 373; Morat, J. P., physiology of the nervous system, 500; Morris, Henry, and McMurrich, J. Playfair, editors, Morris's human anatomy, 608; Morse, Nathan Clark, post-operative treatment, 159; Moynihan, B. G. A., abdominal operations, 300; Naunyn, B., der diabetes melitus, 54; Osler, William, and McCrea, Thomas, editors, modern medicine, its theory and practice, 567; Park, Roswell, the principles and practice of modern surgery, 798; Parker, Charles A., a guide to diseases of the nose and throat and their treatment, 25; Paton, D. Noel, essentials of human physiology, 500; Pauli, Wolfgang, physical chemistry in the service of medicine, 25; Posey, William Campbell, and Spiller, William G., editors, the eye and the nervous system: their diagnostic relation, 438; Powell, William M., Saunders' pocket medical formulary, 25; Pusey, William A., principles and practice of dermatology, 192; Pyle, Walter L., editor, a manual of personal hygiene, 675; Redard, P., technique orthopédique, 501; Rotch, Thomas Morgan, pediatrics, 707; Savage, George H., insanity and allied neuroses, 707; Savill, Thomas D., clinical lectures on neurasthenia, 266; Schaefer, E. A., the essentials of histology, 644; Scudder, Charles Locke, the treatment of fractures; with notes upon a few common dislocations, 868; Simon, Charles E., a textbook of physiological chemistry, 831; Soubeyran, P., et Ardin-Delteil, P., petite chirurgie et pratiques spéciales courantes, 868; Sobotta, Yohannes, atlas and textbook of human anatomy, 120; Steel, Graham, textbook on diseases of the heart, 675; Stelwagon, Henry W., essentials of diseases of the skin, 159; Stimson, Lewis A., a practical treatise on fractures and dislocations, 735; Stewart, Francis T., a manual of surgery for students and physicians, 501; Talmey, Bernard S., woman. A treatise on the normal and pathological emotions of feminine love, 536; the medical record visiting list or physicians' diary for 1908, 868; the physicians' visiting list (Lindsay and Blakiston's) for 1908, 868; the practitioner's visiting list, 1908, 868; Townsend, Charles Wendell, along the Labrador coast, 25; Turner, William Aldren, epilepsy: a study of the idiopathic disease, 122; Wachenheim, Friederick L., the climatic treatment of children, 608; Wallis, Fred C., surgery of the rectum, 472; Whitefield, Arthur, a handbook of skin diseases and their treatment, 193; Wiley, Harvey W., foods and their adulteration, 437; Witthaus, R. A., essentials of chemistry and toxicology, 735; Witthaus, R. A., and Becker, Tracy C., medical jurisprudence, forensic medicine and toxicology, 643.

Brain. Two cases of brain abscess, Kittredge, F. E., 396.

Cancer. Cancer of the male urethra. A report of two cases, Barney, J. Dellinger, 790; letter from London. Monckton Copeman and cancer, C., 545; an abdominal lesion simulating cancer, Cates, Benjamin B., 663; a cancer exhibition, 383; diagnosis of gastric cancer, Chase, Richard F., 71; a case of extensive resection of the stomach for carcinoma, Cobb, Farrar, 110; cancer of colon, White, Franklin W., 296; a case of carcinoma involving the thyroid gland, Withington, Charles F., 328; cancer of prostate. Complete prostatectomy by Loring's method. Two cases of excision of adeno-carcinoma of the rectum, with preservation of the sphincter, Porter, C. A., 819.

Christian Science. Christian Science and the law, 33.

Climate. A search for a suitable climate, Fisk, Samuel A., 252; letter from China. Climate and diseases in Shanghai and Canton, Shattuck, George C., 95; the effect of Florida climate upon acute and chronic disease, Fremont-Smith, F., 813.

Clinical Meetings. Boston City Hospital, 295, 327; Massachusetts General Hospital, 819.

Colon. The technic to be observed in the examination and local treatment of the upper rectum and pelvic colon, Hill, T. Chittenden, 747; a case of non-ulcerative follicular ileocolitis, Stetson, Frank E., and Creeley, Oscar S., 759.

Correspondence. Letter from San Francisco. The plague situation in San Francisco, Brown, Philip King, 717; letter from London. Monckton Copeman and cancer. The hospitals and physical remedial measures. Dr. Dreschfeld, C., 545; letter from London. The ninth Faraday lecture. Osler's working colony for consumptives. An open-air school, C., 653; "prostatectomy in two stages by special technic," Cabot, Pollen, Jr., 653; collective investigation of the poliomyelitis epidemic of the year 1907, committees of the Neurological Society and Section on Pediatrics of the New York Academy of Medicine, 619; Professor Mendel's greatest service to neurology, Knapp, Philip C., 167; an appeal to the American medical profession, Knopf, S. A., 203; Davis memorial fund, Marcy, Henry O., 33; the treatment of typhoid fever by special sera and statistical methods of research, Prince, Morton, 685; hemorrhagic infarct of the intestine, Quinby, William C., 383; on the treatment of typhoid fever with specific sera, filtrates and residues (Vaughan), Richardson, Mark W., 717; "the early diagnosis of pulmonary tuberculosis for the general practitioner," Robinson, Beverley, 415; notes on x-light. Note 203. On the use of fused silica in vacuum tubes, Rollins, William, 779; warm air for inflation of the ear, Shaw, Arthur J., 578; letter from China. Climate and diseases in Shanghai and Canton. Medical practice, Shattuck, George C., 95; letter from Paris. Amateurs of pure science, Spectator, 166; letter from Paris. Calmette's ophthalmo-reaction to tuberculin, Spectator, 414; letter from Paris. Electric sleep, Spectator, 778; letter from Paris. On the abortifacients of syphilis: atoxyl and calomel, Spectator, 578; letter from Paris. On Weil's new treatment of

hemorrhage in hemophilia, purpura and allied conditions, Spectator, 683; letter from Paris. Recent paper from Professor Chantemesse, Spectator, 510; letter from Paris. Taking one's own remedies, Spectator, 310; tuberculosis at the Long Island Hospital, Stone, A. K., 511; Arabian science, Williams, Edward T., 61; Letter from Paris. Ascending and descending processes, Spectator, 876; walking and health, J. B. Blake, 877.

Current Literature. 30, 58, 90, 127, 163, 199, 234, 272, 306, 345, 378, 409, 443, 477, 506, 541, 573, 615, 648, 679, 712, 741, 774, 804, 836, 873.

Cyst. Echinococcus cyst of liver, Balch, F. G., 825; echinococcus cyst of the liver and the gall bladder, Jones, D. F., 826.

Deaths. Babbin, Hosea J., 620; Bailey, Charles H., 878; Belcher, William Nathan, 746; Beyea, Samuel, 312; Boardman, Charles Hodge, 132; Bonney, Franklin, 686; Brauch, Charles Franklin, 416; Bridgham, Charles Burr, 448; Brissett, Henry Rupert, 654; Brower, A. J., 686; Burton, Charles William, 654; Candidus, Pantaleon, 482; Clark, Gaylord Parsons, 384; Close, Seth D., 654; Cowdrey, Arthur Harris, 686; Cropper, Samuel Preston, 878; Daniell, Vivian, 482; Davidow, Aaron, 746; Day, Cushman, 620; Disbrow, Robert, 686; Eltinge, Edgar, 204; Fite, Campbell Colwell, 686; Folsom, Charles Follen, 312; Ford, Albert W., 621; Gallagher, Edward J., 168; Garland, Joseph Everett, 878; Goodwin, Elmer Ellsworth, 878; Gould, Aldred Henry, 512; Gray, Joseph P., 620; Hart, Israel, 34; Heald, William Frederick, 718; Henel, Frank, 654; Hill, Lester S., 416; Holgate, Thomas H., 718; Huntington, Abel, 686; Johnson, William E., 350; Julien, John M., 780; Leslie, Horace G., 312; Lewengood, Samuel, 416; Manahan, Valentine, 546; Martin, Edmond Howard, 686; McElroy, Lee, 168; McLaughlin, V. Plowden, 654; Messemer, Edward J., 350; Nelson, William N., 34; Newby, George, 448; Nordemann, Felix, 448; Norfolk, Walter John, 780; Oberndorfer, Isidor Pierce, 808; Osgood, Hamilton, 96; Otis, John H., 62; Parker, Willard, 34; Pool, Charles Bret, 654; Russell, William G., 780; Schmitt, John Adam, 780; Shepard, A. Warner, 416; Smith, Jonathan Jason, 546; Swasey, John H., 416; Thurlow, John Howard, 482; Waldron, George, 350; Wildes, Thomas, 780; Wimpelberg, Samuel, 132; Winkler, Joseph A., 350; Winne, Lansing B., 384; Winthrop, W. Walton Woolsey, 878; Wise, Peter M., 482; York, Thomas A., 580.

Debility. A study of fifty-one cases of debility in Jewish patients from the Massachusetts General Hospital, Morrison, H., 816

Delirium. Delirium and delirious states, Swift, Henry M., 687.

Dermatology. Verrucæ plantares; their prevalence in boys and in young men, and their pathology, Bowen, John T., 781; report on dermatology, Bowen, John T., and Towle, Harvey P., 531, 561; the president's address to the Sixth International Dermatological Congress held in New York, Sept. 9–14, 1907, White, James C., 513; dermatitis herpetiformis (herpes gestationes), Towle, H. P., 825.

Dexiocardia. Congenital dexiocardia, Doolittle, W. F., 662; a case of acquired dextrocardia associated with advanced phthisis, Young, J. Herbert, 791.

Diabetes. A critical estimate of the fermentation specific gravity of quantitating sugar in diabetic urine, Christian, Henry A., 178.

Diagnosis. On neurological and psychiatric diagnosis, Barker, Lewellys F., 147; the historical development and relative value of laboratory and clinical methods of diagnosis, Cabot, Richard C., 150; diagnosis of gastric cancer, Chase, Richard P., 721; diagnosis and treatment of diphtheria in young children, Webster, F. P., 698.

Diphtheria. Diagnosis and treatment of diphtheria in young children, Webster, F. P., 698.

Editorials. Russell Sage Institute of Pathology, 26; endowment of research in municipal institutions, 27; Boston Floating Hospital, 28; a medical meeting in Turkey, 55; accidents of July Fourth, 55; health inspection in Massachusetts, 86; dermoid cysts of the anterior mediastinum, 86; relief of consumptives, 87; the result of section of the sympathetic in essential epilepsy, 123; plague investigation in India, 124; opportunities for medical women, 125; Boston Consumptives' Hospital, 160; laboratories in the medical clinic, 161; conference on sleeping sickness, 161; fees for life insurance examination, 194; the prophylaxis and therapeutic measures in Cheyne-Stokes's respiration occurring in the nephritides, 195; institutes for medical research, 196; the question of spontaneous generation, 231; American physicians in Germany, 231; report of State Board of Insanity, 232; school for social workers, 268; accuracy of thought in medicine, 269; seventh International Zoological Congress, 269; hemorrhagic infarct of the intestine, 301; report of the Imperial Cancer Research Fund, 302; sixth International Dermatological Congress, 303; deaths by lightning, 303; plague in India, 341; report of the Carney Hospital for 1906, 342; final statistics of July Fourth, 342; the alarmist physician, 374; poliomyelitis in New York, 375; blindness from birth, 375; physical condition of public school children, 405; treatment of inebriety, 406; death of Dr. James Carroll, 439; improved health of school and college students, 439; cocaine and the negro, 440; the development of graduate teaching, 473; future possibilities of expert testimony, 474; popular lectures on insanity, 502; closing of Cambridge School of Nursing, 502; International Congress on Tuberculosis, 537; Boston Directory of Charitable Organizations, 538; report of the Surgeon-General of the Army, 538; a new clinical journal, 539; pharmacists and physicians, 569; the relations of tumors to injuries, 570; the development of the work of the Massachusetts State Board of Health, 609; interchange of medical teachers, 610; an abuse under the pure food law, 161; medical books and book reviews, 645; Professor Joseph Leidy, 646; the frequency of anterior poliomyelitis, 676; the art of prognosis, 677; scientific accuracy and the imagination, 708; employment for the handicapped, 709; rural life for the restored consumptive, 737; tuberculin in dermatology, 738; adolescence, 769; the collective investigation of disease, 769; walking and health, 800; standards of admission to medical schools, 801; report of Surgeon-General, United States Navy, 832; the clinical types of carcinoma of the large intestine, 833; commitment and discharge of the insane, 834; infection from flies, 869, the registration of opticians, 869; report of the Caroline Brewer Croft fund cancer commission, 870.

Epilepsy. Heredity in diseases of the nervous system with especial reference to heredity in epilepsy, Knapp, Philip C., 485.

Expert Testimony. Medical expert testimony, Taylor, E. W., 601.

Factory Inspection. Factory inspection, Wheatley, Frank G., 293.

Fever. The three long-continued fevers of New England, Cabot, Richard C., 281; the treatment of fever cases in the public service, Drew, C. A., 181.

Fractures. Report of a case of fracture into acetabulum with separation at sacro-iliac synchrondrosis without clinical symptoms, Adams, John D., 432; fractured skull with extensive defect of bone, Blake, J. Bapst, 334; a study of seven hundred and fifty fractures of long bones of the lower extremity, with special reference to the cause of delayed union, Paul, Luther G., 255; a portable traction and retentive apparatus for use in fracture of and operations on the lower extremity, Soutter, Robert, 724.

Gall Bladder. Typhoid fever with acute cholecystitis and perforation of gall bladder, Lothrop, H. A., 334; echinococcus cyst of the liver and of the gall bladder, Jones, D. F., 826.

Goiter. The serum treatment of exophthalmic goiter. A review of the literature, Bulkeley, Frank S., 626; exophthalmic goiter, Swasey, Edward, 754.

Gonorrhea. Syphilis and gonorrhea in internal medicine, Willson, Robert N., 631.

Gynecology. Progress in gynecology, Burrage, W. L., 760; the utero-sacral ligaments, Craig, Daniel H., 101; retroversion and its treatment; an analysis of five hundred consecutive cases at the Free Hospital for Women, Graves, W. P., 1; vicarious menstruation with a report of two cases, Larrabee, Ralph C., 217; the gynecological stomach, 239.

Habit Cure. Habit cure, mental and physical, Achorn, John Warren, 260.

Hemorrhage. Two cases of hemorrhage following the removal of the tonsils, Crockett, E. A., 661; a case of chronic otitis media, hemorrhage into the external auditory canal, perforation of the wall of pharynx, with fatal hemorrhage from the jugular vein, Jack, Frederick L. and Verhoeff, Frederick H., 17; hemorrhagic infarct of the intestine, Quinby, William C., 383; letter from Paris. On Weil's new treatment of hemorrhage in hemophilia, purpura and allied conditions, Spectator, 683; pontine hemorrhage, Withington, Charles F., 328.

Henrik Kellgren. Henrik Kellgren and his methods of manual treatment, Cyriax, Edgar F., 490.

Homicide. The question of "justifiable homicide," Cumston, Charles G., 429, 464, 495, 529, 556.

Hydrophobia. Hydrophobia and its prevention, Sylvester, C. P., 97; a case of rabies, Withington, Charles F., 525.

Hygiene. A department of school hygiene, Gulick, Luther H., 113; the contamination of the air of our cities with sulphur dioxid, the cause of respiratory disease, Schaefer, Theodore W., 106.

Ileocolitis. A case of non-ulcerative follicular ileocolitis, Stetson, Frank E., and Creeley, Oscar S., 759.

Immunity. Immunity and therapeutic action, Mays, Thomas J., 695.

Injuries. Ocular injuries from dynamite explosions, Greenwood, Allen, 329; tarsal injuries, Knowlton, John G. W., 636.

Insanity. "Organism X" probably of the coryne-bacterium group: its differentiation from B. diphtheriæ and allied organisms. Its pathogenicity in man, especially in bronchopneumonia and its relation to general paralysis of the insane, Hoag, Louis, 10; report on mental disaase, Stedman, Henry R., 764; the need of popular lectures on insanity, Stedman, Henry R., 483; delirium and delirious states, Swift, Henry M., 687.

Intestine. Rupture of the intestine, Balch, F. G., 825.

Knee. Foreign body in knee, Lothrop, H. A., 334.

Laryngology. Glottic spasm of nasal origin in adults, Conlon, Frank A., 186; case of neurosis of esophagus, White, Franklin W., 333.

Lead Poisoning. Lead poisoning, in a rural community, Cowles, William N., 325.

Ligaments. The utero-sacral ligaments, Craig, Daniel H., 101.

Medical Inspectors. Medical inspectors: their function, Harrington, Charles, 291.

Medical Notes. 28, 56, 88, 125, 162, 196, 232, 270, 303, 343, 375, 406, 441, 475, 503, 539, 571, 611, 647, 677, 709, 739, 770, 802, 834, 870.

Milk. The reaction of some milk modifications to rennet, Illoway, H., 462.

Miscellany. Christian Science and the law, 33; a temperance bureau, 61; Dr. William K. Otis, 61; physical condition of West Point cadets, 238; the gynecological stomach, 239; immunization and the prophet of fresh air, 239; the domestic fly, 349; a cancer exhibition, 383; typhoid fever epidemic at New Jersey State Hospital, 414; the Mary Putnam Jacobi fellowship; 481; the Massachusetts Medical Society. Meeting of the Council, 509; "Kulin polygamy," 618; in honor of Robert Koch, 619; resolutions against contract practice, 619; the International Congress on Tuberculosis, 652; the American National Red Cross, 716; the operative treatment of cancer, 716; free public lectures on medical subjects, 841.

Muscle. The so-called "Ochsner muscle" of the duodenum, Boothby, Walter M., 80; muscle and tendon transference, Bradford, E. H., and Soutter, Robert, 655.

Nephrolithiasis. Some remarks on nephrolithiasis, O'Neil, Richard P., 44.

Nerve Plexuses. A simple method of reconstructing nerve plexuses, Smith, R. M., and Taylor, E. W., 700.

Neuralgia. Neuralgia of the superior maxillary nerve, Lothrop, Howard A., 8.

Neurosis. Case of neurosis of esophagus, White, Franklin W., 333.

Obituaries. Richard Henry Derby, M.D., 58; Sir William Henry Perkin, 89; Sir William Henry Broadbent, 89; Hamilton Osgood, M.D., 90; Emmanuel Mendel, M.D., 127; Sir William Tannant Gairdner, 234; Charles Follen Folsom, M.D., 305; Seneca D. Powell, M.D., 345; Francis Hartman Markoe, M.D., 409; Joel W. Hyde, M.D., 477; Henry Watson Dudley, M.D., In me-

moriam, 505; Alfred H. Gould, M.D., 506; action on the death of Charles Follen Folsom, M.D., 573; resolutions on the death of Richard Henry Derby, M.D., 647; Edmund S. F. Arnold, M.D., 773; George P. Shrady, M.D., 773; Alexander Mactier Pirrie. A martyr to science, 773; Henry Patterson Loomis, M.D., 872.

Obstetrics. A case of obstetrical paralysis in a baby eight days old, Green, C. M., 329; the superiority of primary over secondary Cesarian sections, and the feasibility and advantages of a predetermination of the method of delivery, Reynolds, Edward, 581; painless labor. Report of a case due to a destructive lesion of the spinal cord, Taylor, E. W., 14; dystocia due to fibroids. Intra-uterine death of fetus. Craniotomy, Torbert, James R., 729.

Onyalai. Report on a peculiar disease of tropical Africa called "onyalai," Wellman, F. Creighton, 365.

Ophthalmology. Sympathetic ophthalmology. Conjunctival graft for corneal ulcer, Greenwood, Allen, 329; recent progress in ophthalmology, Standish, Myles, and Hall, William Dudley, 498.

Optometrist. The "optometrist." A warning word, Bossidy, John C., 857.

Otology. A case of chronic otitis media, hemorrhage into the external auditory canal, perforation of the wall of pharynx, with fatal hemorrhage from the jugular vein, Jack, Frederick L., and Verhoeff, Frederick H., 17; warm air for inflation of the ear, Shaw, Arthur J., 578.

Paralysis. Diffuse peritonitis; drainage; intestinal paralysis, secondary enterostomy, with relief of symptoms, Cheever, David, 335; nocturnal paralysis, Coriat, Isador H., 47; some further studies on nocturnal paralysis, Coriat, Isador H., 751; a case of obstetrical paralysis in a baby eight days old, Green, C. M., 329; "organism X," probably of the coryne-bacterium group: its differentiation from B. diphtheriæ and allied organisms. Its pathogenicity in man, especially in bronchopneumonia and its relation to general paralysis of the insane, Hoag, Louis, 10.

Paresis. Post-diphtheritic intestinal paresis, Green, C. M., 329.

Pediatrics. The Roentgen ray in pediatrics, Rotch, Thomas M., 547; progress in pediatrics, Rotch, Thomas M., and Morse, John L., 19.

Peritonitis. Diffuse peritonitis; drainage; intestinal paralysis, secondary enterostomy, with relief of symptoms, Cheever, David, 335; tuberculous ulcer of the ileum. Perforation. General peritonitis. Operation. Death, Leen, Thomas F., and Bottomley, John T., 605; anatomic and physiologic rest of the peritoneum in peritonitis, Robinson, Byron, 634.

Pleura. Malignant disease of pleura, with exhibition of specimen, Vickery, H. F., Richardson, Oscar, and Wright, J. H., 824.

Poliomyelitis. Collective investigation of the poliomyelitis epidemic of the year 1907, Committees of the Neurological Society and Section on Pediatrics of the New York Academy of Medicine, 619; anterior poliomyelitis in the adult, with illustrative cases, Walton, G. L., 779.

Progress. Progress in dermatology, Bowen, John T., and Towle, Harvey P., 561; report on dermatology, Bowen, John T., and Towle, Harvey P., 531; progress in gynecology, Burrage, W. L., 760; progress in the theory and practice of medicine, Christian, Henry A., 222; progress in surgery, Mumford, J. G., 638, 664; progress in physiological chemistry, Ogden, J. Bergen, 114; progress in pediatrics, Rotch, Thomas M., and Morse, John L., 19; recent progress in ophthalmology, Standish, Myles, and Hall, William D., 498; report on mental disease, Stedman, Henry R., 764;

Prostate. The prostate from the surgical standpoint, Benson, Charles S., 519; modern operations for complete removal of the prostate, Cabot, Arthur Tracy, 456; prostatectomy in two stages by special technic, Cabot, Follen, 554; "prostatectomy in two stages by special technic," Cabot, Follen, Jr., 653; a suppurating supernumerary ureter opening into the prostatic urethra, Chute, Arthur L., 385; a case of suprapubic cystostomy on a prostatic; with remarks on technic and indications of this operation, Cumston, Charles G., 788; suprapubic prostatectomy and stone in bladder, Balch, F. G., 825; cancer of prostate. Complete prostatectomy by Loring's method. Porter, C. A., 819.

Psychotherapeutic Movement. The attitude of the medical profession toward the psychotherapeutic movement, Taylor, E. W., 843.

Pylorus. Stenosis of the pylorus in infancy, Scudder, Charles L., 321; case of pyloric obstruction due to ulcer scar and adhesions. Posterior gastro-enterostomy, White, Franklin W., and Lund, F. B., 330.

Raynaud's Disease. Raynaud's disease, Towle, H. P., 836.

Rectal Anesthesia. Rectal anesthesia, Cunningham, John H., Jr., 355.

Rectum. The technic to be observed in the examination and local treatment of the upper rectum and pelvic colon, Hill, T. Chittenden, 747; two cases of excision of adeno-carcinoma of the rectum, with preservation of the sphincter, Porter, C. A., 819.

Rheumatism. A case of acute rheumatism with mixed erythematous and purpuric eruptions, Withington, Charles F., 328.

Rhinology. The correction of malocclusion and its relation to rhinology, Rogers, Alfred P., 784.

Right-Handedness. The origin of right-handedness, Gould, George M., 597.

School Hygiene. A department of school hygiene, Gulick, Luther H., 113.

Societies. RETROVERSION AND ITS TREATMENT: AN ANALYSIS OF FIVE HUNDRED CONSECUTIVE CASES AT THE FREE HOSPITAL FOR WOMEN.*

BY W. P. GRAVES, M.D.,

First Assistant Visiting Surgeon, Free Hospital for Women; Assistant in Gynecology, Harvard Medical School.

ALTHOUGH retroversion of the uterus, next to plastic surgery of the vagina, is the most common condition which gynecologists have to treat, and one about which more has been written and for which more operations have been devised than any other, there are still many points of disagreement among surgeons, especially with regard to causation and treatment. It was with the hope of gaining information on these disputed issues that I have been led to investigate the subject by a study of cases operated on in recent years at the Free Hospital for Women. The method which I have pursued was to tabulate from the history of five hundred consecutive cases preceding June 1, 1906, such facts as would give information on the symptomatology, causation, nature of the operation and after-results. A letter was then written to each patient asking an answer to a series of questions covering symptomatic results of the operations, later pregnancies and present conditions, with the request also to report in person at the out-patient department.

CAUSATION.

It is of great importance that the surgeon should have an intelligent knowledge of the causation of retrodisplacements, on account of the necessity of applying the proper operation to the individual case. This subject is one of a very wide difference of opinion, and one which is frequently a matter of contention.

In order to discuss intelligently the causation of retrodisplacements, it is necessary to consider briefly the question of the supports of the uterus. The extremely complicated set of supporting structures with which nature has endowed the uterus in order to meet the extraordinary changes in size and position which it is its function to undergo, may, to all practical purposes, be reduced to comparatively simple terms. An idea of what constitutes the support of the uterus can best be appreciated during the performance of a complete hysterectomy, which consists merely of a systematic severing of the supporting attachments of the uterus.

During such an operation one becomes impressed with the fact that the uterus is supported around its middle by a diaphragm of tissue which has its ultimate support from the walls of the bony pelvis, and which has in it certain fibromuscular thickenings which are termed ligaments. There are, first, the lumbo-ovarian ligaments, which act to limit mildly the lateral antero-posterior mobility of the uterus. That they are real ligaments and have some true function is shown by the severe malposition of the uterus which they may cause when they are abnormally developed. It is, however, during embryonal life that they possess their chief function, for at that time they are the most important supporting attachments of the pelvic organs.

Next come the round ligaments, which are strong elastic structures that help to preserve the forward position of the uterus. They exert a gentle but firm and effective force to keep the uterus in its forward position resting on the bladder, their elastic nature allowing for the antero-posterior play caused by the constant change in the size of the bladder. The round ligaments have little or no office in maintaining the uterus at its physiological level in the pelvis. The broad ligaments serve to limit the lateral mobility of the uterus, and support it to a considerable extent through numerous smooth muscle fibers and elastic tissue, most highly developed along the course of the uterine vessels. We then come to the three structures of the pelvic diaphragm which are most important for sustaining the uterus in its physiological plane, namely, the uterovesical and uterosacral ligaments, and the fibromuscular vault of the vagina. The uterovesical and uterosacral thickenings of the pelvic diaphragm act as a swing to support the uterus antero-posteriorly between the sacrum and pubes. They are tough, rather inelastic bands, and are often of great strength, as is shown by the difficulty which one occasionally encounters in cutting them in operations on nulliparous women. In cutting through the vault of the vagina one encounters the last and most important tissue which maintains the uterus in its normal position, and one which is the last to give way when all other supporting structures are gone. It must be remembered that the uterus and vagina actually constitute one organ, the muscular connection between the two being very strong and of great importance. Regarding, then, the vagina as a constituent part of the uterine system, it follows that whatever supports the vagina also supports the uterus, and in my estimation the powerful attachment of the vagina to the rami of the pubes is the most important of all the supporting structures of the pelvic floor. The gradual weakening of the round ligaments may result in a partial retroversion; the gradual weakening of the uterosacral ligaments will result in retroversion and partial prolapse; and the gradual weakening of the uterovesical ligaments will result in cystocele and partial prolapse; *but when the vaginal attachment to the pubes* gives way, everything falls and procidentia results.

With this brief summary of the chief supports of the uterus, it is natural to conceive that the most obvious cause for weakening these supports, with the resulting malposition, would be the condition of pregnancy and childbirth, where all the pelvic tissues are profoundly stretched and distorted from their usual position. It is readily apparent that the heavy subinvoluted uterus, during the period of convalescence, with

* Read before the Boston Obstetrical Society, April 23, 1907.

the patient lying on her back, would have a strong tendency to overcome the damaged elasticity of the ligaments and thus result in permanent displacement. This factor as a causation of retroversion is so obvious and so universally accepted that in making my statistics I have tabulated as a result of childbirth all cases of non-adherent retroversion in women who have borne children. This class of cases of retroversion amounts to 51% and agrees with the generally accepted view that pregnancy and childbirth constitute the most common causes of retroversion.[1]

The second most common cause for retroversion found in my series is pelvic inflammation with the formation of adhesions. These adhesions originate from an infection through the tubes, as is well known, and form most commonly on the posterior surface of the pelvic organs, and have a marked tendency to draw the uterus backward into the posterior cul-de-sac. Not only is the uterus drawn backward by adhesions immediately on its posterior surface, but it is also dragged in the same direction by the adhesions which draw the tubes and ovaries deep into the posterior lateral pockets of the true pelvis. Such a retroversion may take place without the essential weakening of the supporting structures of the uterus, it being less common to find the uterus in the last degree of retroversion, a point which, as may later be seen, would have some bearing on the choice of operative treatment.

Retroversion of this kind constitutes 20% of my series of cases. The causes of pelvic inflammation which bring about this adherent condition of the uterus in a posterior position are, in the great majority of cases, gonorrhea and sepsis following miscarriage.

The third most common cause shown by my statistics is what I should term developmental. The term "congenital retroversion" is one which has long been in use, but is one which is inexact and does not take into account the period of time at which these malpositions take place. The uterus, as I have observed it in a number of dissections of full-term children dead at childbirth, is an unimportant and extremely undeveloped organ. It lies high in the pelvis, and in the cases that I have seen has been pressed and flattened against the sacrum by the pressure of the small intestines, so that conditions of retroversion, anteflexion and retrocession, which are ordinarily called congenital, cannot, at this period of life, be considered as existing. The uterus grows slowly during the early life of a child, it being extremely rare that it makes known its existence by either physiological or pathological processes. At the age of puberty, however, ensues a process of extraordinarily rapid development, and it is then that it assumes approximately the size and type of that of mature womanhood, or else, retarded in its development, either intrinsically or in association with other organs, suffers the malpositions or distortions which are ordinarily designated as congenital. Such malpositions are most commonly represented by permanent anteflexion, retroversion and retroflexion, and anteflexion combined with retroversion.

The diagnosis of a developmental retrodisplacement is, as a rule, not difficult to make, and this could be done with a reasonable degree of accuracy both by direct examination and by a study of the history and operative findings in the hospital cases that I have investigated. A large number of cases which I have classified as developmental showed unmistakable stigmata of developmental defects; for example, abnormally short posterior vaginal wall, short uterosacral ligaments, together with anteflexion and infantile character of the cervix and fundus, short lumbo-ovarian ligaments, bicornate form of the uterus, hypoplasia of one side of the uterus and congenital absence of one ovary, defective growth of the round ligaments and other interesting conditions, which leave no doubt whatever of the real cause of the retroversion. In other cases, where an Alexander's operation had been done, and the condition of the pelvis not recorded, the retroversion was classified as developmental where symptoms of severe dysmenorrhea or sacral backache had existed since the institution of menstruation. The majority of these cases were young women, usually under twenty-five, or young married women who were sterile.

No case was included in this class where there were evidences of adhesions, a point which calls to mind the prevalent belief that the uterus which has been retroverted for a considerable length of time becomes adherent. The falsity of this theory is, of course, apparent when it is considered that there is no more reason for the uterus to become adherent while lying in contact with the peritoneal surface covering the upper portion of the rectum than while in contact with the peritoneal surface covering the upper portion of the bladder. It may be added that in none of the cases to which a developmental origin could be assigned in my series, even where the patient had menstruated for twelve or fifteen years, were there any adhesions.

It is undoubtedly true that some cases of retroversion occur during the period when the uterus is developing, as a result of habitual constipation, or of keeping the bladder distended, a frequent habit among young girls. Such uteri might present no evidence of developmental defect other than a weakening of the ligaments.

I regard the consideration of this developmental type of cases as of very great importance, for it is probably true that many of the so-called acute retroversions which are regarded as so common, belong to this class.

Cases of developmental retroversion constitute 16% in my classification.

The fourth most common cause of retroversion, and occupying 8% in this series, is the displace-

[1] A certain element of error in the classification is unavoidable. For example, a woman with retroversion following childbirth, or one with developmental retroversion, may later suffer from adhesive pelvic peritonitis. In such cases a mistake might be made in assigning the cause for the retroversion. Doubtful cases of this kind did not occur with sufficient frequency to affect materially the final classification.

ment due to pressure of pelvic tumors; for example, ovarian cysts, uterine fibroids, extra-uterine pregnancy and broad ligament tumors. The pressure of these tumors exerts very little effect on the essential supports of the uterus, and it is not infrequent to see the uterus immediately assume its normal former position after removal of tumors, even of long standing. This was seen in one case where I recently removed a large pedunculated fibroid with a twisted pedicle which was growing over the frontal portion of the fundus. The uterus was retroverted backward and to the right, and firmly held there by the tumor above it, which measured six inches in diameter. The size of the tumor proves that the uterus must have been in this position for a considerable number of months at the very least. After the removal of the tumor the uterus immediately assumed a perfectly normal position. In another case where I found an enormous mass of organizing blood clot, the result of an extra-uterine pregnancy, which had existed in the abdomen for five weeks, the uterus, though held in a position of retroversion during all this period, immediately assumed its normal position after removal of the mass in the pelvis.

There is left 4% of cases for which I have been unable to make a satisfactory classification. In a few of them the histories were incomplete. Most of them were unmarried or sterile women between the ages of thirty and forty, who had non-adherent retroversion, but whose symptoms dated back for only a few years. In none of them was there any history of an accident or fall, or an acute onset. In my own opinion they would undoubtedly either fall into the class of developmental retroversion where symptoms were absent, a condition which I have not infrequently noted in young women, or be included among those individuals whom Tuffier has aptly described as possessing a physiological inferiority of tissues. Here the retroversion must be considered as a gradual process similar to floating kidneys or other visceral ptosis.

SYMPTOMATOLOGY.

The symptom complex of a typical case of retroversion is so characteristic that it is very frequently possible to make a correct diagnosis from the history alone. A woman who suffers from a constant sacral backache, ovarian pain, dysmenorrhea or profuse menstruation, and who is nervous and constipated, and suffers from frequent headaches, presents the typical history of a patient with a retroverted uterus. No one of these symptoms, however, is pathognomonic of the condition, the most nearly constant being sacral backache, which occurred in 76% of all the cases. This symptom is usually the most prominent and is the one which, as a rule, brings the patient to consult her physician.

The second most common symptom is ovarian pain on one or both sides, more frequently on the left side and occurring in 62% of the cases. Ovarian pain is probably due to a disturbance in the circulation of the ovary caused by the malposition of the uterus and a certain amount of prolapse of the ovaries, which usually takes place. Microscopically these ovaries are apt to show cystic degeneration of the follicles or subinvolution of corpora lutea. The ovary is usually edematous and is larger and heavier than normal.

Some disturbance of menstruation, though occurring in only 56% of the cases, may, nevertheless, be regarded as one of the cardinal symptoms of retroversion, together with backache and ovarian pain. This symptom also is due to a disturbance in the circulation of the uterus, and must be referred rather to a mechanical obstruction than to a faulty control of the nervous system. In developmental cases the menstrual irregularity is much more constant and usually takes the form of a dysmenorrhea, while in cases caused by childbirth the complaint more often is of too frequent and profuse menstruation, a condition which is the result of a gland hypertrophy of the endometrium.

It is a question whether constipation should be regarded as a cardinal symptom or as a referred symptom due to a general constitutional deterioration resulting from the retroversion. I am inclined to regard many cases of constipation directly due to the influence on the rectum caused by the pressure of a retroflexed fundus. Constipation appeared as a pronounced symptom in 51% of all the histories. Whether this percentage is larger than would appear in the histories of 500 women taken at random who were not suffering from any pelvic trouble I am unable to say, but the fact that 48% of these cases were either cured or greatly relieved by the operation is at least suggestive that many cases of constipation are directly due to the uterine displacement.

Seventy-one per cent gave nervousness as one of the principal symptoms, while a considerable number complained of frequent or constant headaches, usually locating the pain in the back of the head and neck. Many of them complained of headache only at the menstrual periods, and in view of the fact that a considerable portion of those suffering from headaches reported great relief or cure after operation, one should not neglect the consideration of retroversion in diagnosing the cause of headaches among women.

Viewing symptomatology from a general standpoint it may be said that women suffering from retroversion caused by childbirth are far more apt to have the symptom complex, backache being the most prominent, than are those with retroversion from other causes. The most characteristic symptom in inflammatory cases is ovarian pain, while the most characteristic symptom in developmental cases is dysmenorrhea. It is not uncommon to find young women with developmental retroversion having no symptoms whatever.

TREATMENT.

A discussion of the treatment of retroversion involves first the question whether it shall be

operative or palliative, and, secondly, if operative, a correct choice of the great number of operations which have been devised for the relief of retroversion. The treatment of the cases in my series having been operative, the question as to its feasibility can be answered by an inquiry into the anatomical and symptomatic results of the operations. Information on this point was obtained by a letter sent to each patient requesting a statement regarding her cure, relief or non-relief from the operation in general, and from the particular symptoms of backache, ovarian pain, menstrual disturbances, constipation and headache. In considering the statistics which I gathered from these letters, it must be borne in mind that only a small per cent of the operations were uncomplicated by other operations performed at the same time, as, for example, laceration of the cervix and perineum, repair or removal of the tubes and ovaries, removal of tumors, the repair of hernias, etc., so that the answer as to whether the patient was cured by her operation does not in all instances imply an answer as to whether she was cured or relieved of the condition of retroversion. Inasmuch, however, as the cardinal symptom of sacral backache occurs in the great majority of cases, the answer to the question of relief or non-relief of that symptom will give approximate information concerning relief or non-relief from the condition of retroversion.

Two hundred and sixty-three patients answered the circular letter in a satisfactory manner. Of this number 86% stated that they were either completely cured or much relieved by the operation. Considering the numerous additional operations, many of them serious ones, which complicated the operation for retroversion, this percentage must be regarded a satisfactory one, and compares favorably with those published from other hospitals. It is interesting to note that those who were entirely cured or much relieved of the symptom of backache amounted to 85%, in comparison with 86% of those cured or much relieved by the operation. This would tend to show that in the great majority of these cases, though complicated as many of them were, the retroversion was the chief cause for suffering on the part of the patient. It is also interesting to note in this connection that the anatomical recurrences of retroversion after the operation, which, as will be seen, I have approximated at 15%, corresponds closely to the percentage of patients who stated that they received slight or no relief from the operation.

Seventy per cent of those having ovarian pain, and 70% of those suffering from some disturbance of menstruation, were either cured or relieved. Forty-eight per cent were cured or relieved of constipation.

With these figures in view and in consideration of the fact that the great majority of retroversion cases are complicated by other surgical diseases any argument as to the comparative merits of treatment by pessaries or tampons is practically out of the question excepting in a few selected cases.

In the days when pessaries were the only available treatment for retroversion of all kinds, Dr. F. H. Davenport was able to accomplish satisfactory results in 31%. Although this shows that such treatment is inapplicable in the majority of cases, it nevertheless proves that pessaries should be still kept as one of the resources of the surgeon, and not be absolutely disregarded.

One must in this connection take into account the danger to life involved in the operative treatment of retroversion. The mortality in this series of cases amounts to 2, one case dying six hours after operation, from heart embolism as shown by autopsy, the other case dying from the unusual condition of general peritonitis caused by the staphylococcus albus. This last case was complicated by the removal of a very adherent appendix. In considering this excellent mortality record it must also be borne in mind that many of the operations were complicated by serious and dangerous pelvic conditions.

DISCUSSION OF OPERATIONS.

Having established then the fact that in the great majority of cases operative treatment is advisable, it remains to choose intelligently the best method of surgical procedure. It is said that as many as 52 different operations have been devised for the treatment of retroversion and this large number of operations is frequently presented as a proof of the unsatisfactory results of operative measures.

In order to gain information of value with regard to the merits of the operations employed at the Free Hospital for Women I have tabulated the number of times each operation was performed and have computed a comparative set of percentages which each operation bears to the anatomical failures. I have found, all told, 60 recurrences of retroversion after operation. This constitutes 12% of the entire series. The number has been made up both from a large number of patients whom I have personally examined from eight months to several years after operation and from entries in the hospital records made by other members of the staff. Although the Free Hospital offers very unusual opportunities for following post-operative cases, there are some cases which have never been seen after leaving the hospital, and a certain number of recurrences have undoubtedly been overlooked. With this in view I have estimated that the recurrences have probably amounted to at least 15% of the entire number.

Though numerous methods have been employed by different operators, in my series I have tabulated the results only of those operations which have been frequent enough to furnish statistics of value, and this list includes Alexander's operation, ventro-suspension, ventro-fixation, and internal shortening of the round ligaments. Alexander's operation was performed 191 times with a known recurrence of 13%. Ventro-suspension and ventro-fixation were performed 267 times with a known recurrence of 9%. Internal shortening of the round ligaments was

performed 35 times with a known recurrence of 31%.

Using these figures as an assistance, I shall now attempt to discuss the comparative merits of these operations with a view both to the anatomical derangements which they are capable of repairing and also to their symptomatic results.

Alexander's operation. — This operation was originally devised during the days of constant sepsis to avoid the necessity of opening the abdominal cavity, and was in those days, of course, a most ingenious method of avoiding danger to life and served as a great benefit to suffering womankind. Considering now that in the light of our present surgical technic the original danger, to obviate which the Alexander's operation was devised, has been so far removed as to be of little weight, the question arises, "Is the operation a sufficiently satisfactory one?" Thirteen percentage of recurrences, even though it represented the true maximum, is much too high for a surgeon to view with equanimity. This high percentage of recurrences, as I have been able to prove by my personal examinations and by the history of after results, is largely attributable to the factor which constitutes the real defect in the operation, namely, the presence of pelvic adhesions, which were not diagnosed at the preliminary examination. In many such cases, where the adhesions are not particularly dense or where there is an unusual amount of yielding tissue, to which the uterus and adnexa are attached, it is possible to draw the uterus up to a position of comparative normality for a short period of time, but the continual dragging on the back of the uterus eventually overcomes the tension of the recently shortened ligaments and the uterus reverts to its former position often before the patient leaves the hospital. Other objectionable features of the operation are hernias and sepsis. Hernias occur as a result of an unskillful performance of the operation and are sufficiently frequent to make it inadvisable for any inexperienced operator to attempt it. Sepsis in the wounds is shown by the hospital records to be of frequent occurrence and the danger of this complication has not been entirely removed, even in most recent cases performed with every precaution of asepsis.

Mechanically speaking, reduced to simple terms, the uterus by this operation is practically suspended to the abdominal wall from its two weakest points. The ligaments themselves are frequently weak and ineffective, even at their uterine attachments, as is often seen in developmental cases, while the inability of even the most experienced surgeon sometimes to find the round ligament in the inguinal canal is a not unfamiliar spectacle. Notwithstanding all these objectionable features, it must be admitted in the cases that I have examined where Alexander's operation has been successfully done the anatomical and symptomatic results have been excellent, so that in selected cases given an easily replaceable uterus and a surgeon with good technical skill the operation may be regarded as a most desirable one.

Ventrosuspension and ventrofixation. — It is necessary to consider these two operations in conjunction in this series of operations on account of the indefinite manner in which the two terms have been used. Ventrofixation in the hospital records has been used where the supporting stitch has included the *aponeurosis covering the rectus muscle*, while ventrosuspension is used where the stitch includes the peritoneum alone or the peritoneum and part of the muscle. Strictly speaking, ventrosuspension should be used exclusively when the supporting suture passes only through the peritoneum, including no other structures of the abdominal wall. As a matter of fact, in the majority of so-called ventrosuspensions performed in this series the suture was actually passed through the rectus muscle and peritoneum, and really constitutes more nearly a ventrofixation than a ventrosuspension. As it has been impossible to differentiate exactly between these two procedures, I am compelled to consider suspension and fixation under one category. There were 267 of these operations with a known recurrence of 9%. Notwithstanding the confusion existing between the two terms suspension and fixation, valuable information could be gained from a study of the recurrences as to the most efficient method of fastening the uterus to the abdominal wall. Two thirds of the recurrences in this class of cases are attributable to the method of passing the suture only through the peritoneum, and as this method has been comparatively little used, the recurrences where the suture had passed through the muscle or through the fascia would be reduced approximately to less than 5%, not an ideal, but nevertheless a fairly satisfactory, result.

As a matter of fact there is probably little anatomical difference between a skillfully done ventral fixation and a successful ventral suspension. In each there is an adhesion formed between the fundus of the uterus and the anterior abdominal wall of sufficient strength to hold the uterus forward and maintain it at its physiological level in the pelvis. The stitch itself counts for very little after the adhesion has been formed. The reason that a ventral suspension performed by merely passing a ligature through the peritoneum gives uncertain results, is because the peritoneum may be pulled into a long string without the formation of an adhesion sufficient to hold the uterus to the abdominal wall. However, in many cases such an adhesion does form and the operation remains successful. In passing a suture so as to include the muscle or fascia the formation of an efficient adhesion is much more nearly insured. The danger attending a ventral fixation is of the formation of too dense an adhesion, so as either to immobilize the uterus or to cause dystocia in future pregnancies. The surgeon in attaching the uterus to the anterior abdominal wall should bear in mind possibilities of too weak or too strong an adhesion, and the result of the operation, therefore, depends largely on his technical skill. Where the uterus has been effectively attached to the abdominal wall, symptomatic

results and results in pregnancy in the present series of cases have been excellent.

Intra-abdominal shortening of the round ligaments. — This operation was performed thirty-five times and there is a known recurrence of 31% — an extermely bad showing. Various methods were used, the most common one being that devised by Wylie. There has been also a considerable number of these cases which have been examined by me before discharge from the hospital, where the uterus was sufficiently held in a forward position, so that it could not be called a recurrence, but where, nevertheless, there existed a certain amount of sagging in the pelvis, with corresponding symptoms. Fortunately only comparatively few of these operations have been done, the results from them being either symptomatically or anatomically in the great majority of cases bad.

The following case illustrates well the experience with intra-abdominal shortening of the round ligaments, as well as that of ventral fixation.

Mrs. T., age thirty-two, two children, one miscarriage. Operated on Oct. 31, 1899. Removal of dermoid cyst. Wylie's intra-abdominal shortening of the round ligaments. At the time of discharge the uterus was reported as in the first degree of retroversion.

June 5, 1900, the uterus having become entirely retroverted, a second operation of shortening of the round ligaments was performed. The uterus, however, continued to sag, and on Jan. 22, 1901, ventral fixation was performed.

Sept, 14, 1902, the patient had a normal labor.

April 24, 1903, the uterus was in good position.

Having thus reviewed the surgical experience of the hospital in these retroversion cases, it is in order to inquire what lessons may be learned from them. Bearing in mind the fact that the uterus is essentially supported around its middle by a thick diaphragm attached ultimately to the bony walls of the true pelvis, it is obvious that in the great majority of cases there exists some defect in this main central support. It can, in fact, be shown in most cases that besides the backward displacement of the uterus, there is some sagging of the main supports. This is almost universally true in cases due to childbirth, in chronic cases of physiological inferiority, and in a number of developmental cases. It is less frequent in cases due to adhesions, and sometimes entirely absent in cases due to the pressure of tumors. It will therefore be seen that treatment in order to meet the great majority of retroversion cases must overcome this sagging of the diaphragmatic support. In order to solve this mechanical problem it is conceivable that it may be done in three different ways: first, by supporting the diaphragm from below, as is done to a certain extent by the use of pessaries; secondly, by a complicated operation which would restore each essential structure of the diaphragmatic support to its proper function, and, thirdly, by suspending the uterus from above. The first method, namely, that of using a pessary is entirely inefficient, excepting in a few cases, and can be usually disregarded. The second method of operating on the individual structures of the pelvic diaphragm has been attempted with some success, notably by Bouvé, who dissects out and restores the uterosacral and uterovesical ligaments. Even as complicated an operation as this meets only part of the requirements, and it is inconceivable that in many cases the uterus could be fully and permanently restored to its physiological level in the pelvis.

The reduplication of weakened and stretched-out ligaments is mechanically not an operation to be relied upon, as has been shown by experience in shortening the round ligaments internally, and the reason of this is that the ultimate attachments of these ligaments remain exactly as they did before the operation. These attachments have at one time proved inefficient, and it is reasonable to suppose that when the same forces again work against them the future result may be similar.

There remains then only the method of suspending the uterus from above. The only available point of permanent support is the anterior abdominal wall, and though it seems to be distorting natural anatomical relations to fix the uterus in this manner, nevertheless it has been shown by repeated experience that the abdominal wall is an admirable support to the pelvic organs. The elasticity, strength and plasticity of the abdominal wall make possible the performance of operations by which pelvic organs can be attached to it, even under great tension, without corresponding pain, bladder trouble, or symptoms of any kind, as has been shown by the repeated successful results in the operation of vaginapexy. A uterus firmly attached to the strong and elastic abdominal wall depends no longer on the diaphragmatic support of its center and lower third, and symptoms previously existing by deficiency in this support may be completely relieved. Any operation, therefore, like the internal shortening of the round ligaments which tends merely to restore the uterus to its anterior position, but which does not relieve the diaphragmatic support at all, cannot be expected to attain symptomatic results comparable with some method of attaching the uterus to the abdominal wall.

Having established this premise in our mechanical reasoning, it remains to choose the best method of suspending the uterus from above, and it is a well-known fact that the symptomatic and anatomical results attained by an effective ventrosuspension or fixation are excellent. The objections to this method, however, are, first, the long ribbon of tissue after a ventral suspension causing danger of strangulation of the bowel, and, secondly, evil results obtained in a subsequent pregnancy. The answer to the first objection would be never to perform a ventrosuspension by passing the ligature *only* through the peritoneum, for not only does the retroversion following such a procedure frequently recur, as we have seen in my cases, but it is usually only after such operations that the long peritoneal band of tissue

is formed. The second objection, namely, the danger of dystocia in future pregnancies, is a valid one and one which by no means should be disregarded.

Of the cases, ventrofixation and ventrosuspension, which answered my inquiry as to future pregnancies, 27 reported one or more conceptions, 4 of them being pregnant at the time of reporting. Six of them had miscarried, 1 of these miscarriages being known to have been induced. One reported pain in the lower abdomen during the nine months. One who was pregnant reported pain in the site of the wound. All others reported no trouble, 2 of them saying that they had had less trouble than at previous childbirths. Two had had twins. It will thus be seen that of the 26 cases of ventrofixation, the only difficulties noted were, 6 miscarriages and 2 cases with pain in the lower abdomen during pregnancy, the conception being successful in one of them. This certainly is not a bad record, especially as the percentage of miscarriages corresponds nearly to the accepted percentage of pregnancies in general, namely, 20%. There were in all 48 cases who reported conception after an operation for retroversion. Twenty-six, as we have seen, were after cases where the uterus was attached to the abdominal wall, 22 followed Alexander's operation or internal shortening of the round ligaments. None of these cases had trouble at childbirth. The case which suffered most during pregnancy was one which followed an Alexander's. This case was one whom I examined when she was about four months pregnant. She was suffering intense pain in the two inguinal regions, and though I did not see her again until after the birth of her child, which was successful, she reported that she had spent three months in a hospital suffering greatly from this same pain.

It must be admitted, however, that cases of rupture of the uterus and Cesarean section following fixation have occurred, and the surgeon should bear in mind always that he is taking this remote risk in performing the operation on a woman in the child-bearing period.

It will thus be seen from the foregoing that outside of the intra-abdominal shortening operations the surgical treatment of retroversion has by the methods which have been employed been fairly satisfactory, and with the exception of a mortality of $\frac{1}{8}$ of 1% there have been no untoward results. During the past year for ordinary cases, where it has been thought advisable to open the abdomen and where adhesions have not been too extensive, or where the pelvic diaphragm has not been too greatly relaxed, the operation usually designated as Mayo's internal Alexander has been very generally adopted at the Free Hospital. The results from this operation give excellent promise. It possesses all the advantages of Alexander's operation and most of the advantages of fixation, without the defects of either.

The operation, as is well known, is a modification of Gilliam's operation and consists in drawing the round ligaments up through the internal rings and joining them at the middle line of the abdomen above the rectus muscles and below the fascia, thus avoiding the undesirable weakening of the fascial covering which exists in Gilliam's operation.

The technic of Mayo's operation should be carefully observed and is briefly as follows: A median incision is made, the round ligament of the right side is then grasped by a pair of curved clamps at the junction of the middle and outer third. The assistant holding this clamp draws the ligament toward the median line, pulling the peritoneum at the point where the round ligament enters the abdominal wall into the form of a funnel. A pair of curved clamps with narrow blades is then inserted between the fascia and rectus muscle of the right side and pushed directly to the internal ring and down into the funnel of peritoneum, formed by the traction of the round ligament. It is then pushed along the course of the round ligament still underneath the peritoneum and made to grasp the ligament at the point where the other clamp holds it. The ligament is then drawn up through the internal ring and out to the median line under the fascia, the clamp at no time entering the peritoneal cavity. This procedure is then carried out on the left side and after the peritoneal wound is closed in the median line the two ligaments are drawn together over the rectus muscles and united by several interrupted sutures. The operation is a simple one to perform. It has been done many times at The Free Hospital for Women and the results so far have been universally excellent.

To summarize, then, my conclusions, with regard to treatment, I would make the following statement:

In a case where the uterus can be easily replaced and will remain in position and there is no necessity of inspecting the abdominal cavity, Alexander's operation may be recommended. Where it is desirable to open the abdomen and where there are no excessive adhesions and no marked relaxation of the diaphragmatic support, Mayo's internal Alexander is the operation of choice. In cases of many adhesions and marked retroflexion, or with much sagging of the diaphragmatic support, the uterus should be attached to the abdominal wall in a manner so that it will stay, the exact method of attachment being a matter of choice by the individual surgeon, the question of future childbirths never being disregarded. Attachment of the uterus to the abdominal wall by a suture merely through the peritoneum is an inefficient method of ventral suspension. Intra-abdominal shortening of the round ligaments is an inefficient treatment for retroversion.

Prolapse and procidentia. — The subject of prolapse and procidentia is so closely related to that of retroversion that it is necessary to mention it in a discussion of this subject. In these cases, as has been pointed out, the pelvic diaphragm has partially or completely lost its integrity as an element of support. It has been shown that the only efficient substitute for this

support is, primarily, firm suspension from above, and that the only available point of suspension is the anterior abdominal wall. In cases of extreme procidentia the operation of vaginapexy, devised by Dr. William H. Baker, the operation of colpo-orrhaphy devised by Dr. Polk and similar ones by Dr. Crile and others, where the vagina itself is fixed to the anterior abdominal wall, have entirely revolutionized the eventual success attending operations on these conditions. This subject is, however, so important as to require special study and is mentioned here chiefly to emphasize the use to which the anterior abdominal wall may be put in supporting the pelvic organs.

NEURALGIA OF THE SUPERIOR MAXILLARY NERVE.

BY HOWARD A. LOTHROP, A.M., M.D.,
Instructor in Surgery, Harvard Medical School; Assistant Visiting Surgeon, Boston City Hospital.

A PERIPHERAL OPERATION TO REACH THE DENTAL BRANCHES.

NEURALGIA of the trifacial nerve is of common occurrence, but only in the very chronic and severe cases are all the branches involved. For a period, at least, the pain is referred to one of the divisions and, perhaps most commonly, to the superior maxillary nerve. In a small majority of the cases a definite cause may be found, such as some general disease, — malaria, diabetes mellitus, etc., or there may be a definite local lesion, — scar tissue, exostoses pressing on nerves in bony canals, some dental inflammation, an undescended tooth, etc. Occasionally, the exciting cause may be some lesion in a region supplied by branches of the fifth nerve. A definite neuritis may exist. On the other hand, in the great majority of these cases the cause is not evident and on subsequent examination of the excised nerve nothing pathological is found.

This paper will consider only the second or superior maxillary division of the fifth nerve for the purpose of suggesting a method of intercepting the nerve supply of the teeth of the upper jaw when these branches are involved and it is desired to resort to one of the so-called peripheral operations.

Anatomy. — The second division leaves the skull by the foramen rotundum to reach the spheno-maxillary fossa. Here are given off several branches, viz., the temporo-malar passing into the orbital fossa to be distributed eventually to the malar and temporal regions, the branches to Meckel's ganglion and the posterior dental nerves. The latter go forward to reach the posterior aspect (zygomatic surface) of the superior maxilla. There are two or three trunks which give off filaments to the gums and adjacent portion of the cheek and then enter the substance of the maxilla, passing through bony grooves and, eventually, through canals to reach the roots of the molar teeth; terminal branches pass forward to help form a plexus with branches of the middle and anterior dental nerves.

The main trunk of the superior maxillary nerve passes through the sphenoidal fissure into the orbit and thence through a bony canal on the floor of the orbit to make its exit at the infra-orbital foramen. Dental branches are given off in this canal. If there are any middle dental branches they pass outward and downward in the wall of the maxilla to reach the bicuspid teeth; if absent, these teeth are supplied from the plexus formed by the anterior and posterior dental nerves. Just before the main nerve emerges from the infra-orbital foramen it gives off the anterior dental nerve which enters a minute canal and passes through the substance of the maxilla to be distributed to the canine and incisor teeth and backward to complete the dental plexus. There may be two minute ganglia on this plexus.

After emerging from the infra-orbital foramen the main trunk terminates in its final branches of distribution, — the labial, nasal and palpebral nerves.

The main trunk of this nerve is readily accessible for a considerable distance into the orbit and, although the anterior dental nerve be cut off, the posterior dental nerves remain intact and through the dental plexus there would still be communication with all the teeth. The desire to intercept all the dental nerves without resorting to the more serious and disfiguring operation of reaching the nerve in the spheno-maxillary fossa was the occasion of devising the method described below.

Treatment. — Drug treatment for neuralgia which persists for any considerable period is discouraging. Acute attacks of neuralgia are not uncommon, and these tend to disappear permanently upon the removal of some obvious cause, such as exposure to cold, errors in diet, etc. The cases due to specific organisms disappear under special treatment. But the chronic recurring attacks yield only temporarily to drugs until finally nothing medicinal seems to afford relief. The benefit from electricity is doubtful and rarely lasting, while massage generally does harm. Occasionally some definite local cause is discovered, such as a lesion in the nose, pressure on a nerve trunk, or disease of the teeth, and the removal of such cause is followed by permanent relief.

In the majority of cases, however, no cause can be found, and eventually no drug treatment gives relief. The suffering is so intense that the patient consents willingly to surgical intervention and some sort of an operation is the ultimate outcome.

There are two general types of operation, the peripheral and the central. The former has to do with excision of some portion of the main trunk or its branches distal to the foramen rotundum; the latter is an intracranial operation whereby the nerve trunk and a part or the whole of the gasserian ganglion are removed.

There are several methods of approaching the nerve at the infra-orbital foramen so as to remove more or less of the main trunk, even as far back as the spheno-maxillary fissure. All these methods destroy the anterior dental nerve, for this is given off just before the main trunk leaves this foramen, but none of these superficial operations

destroy the middle and posterior dental nerves. If the pain were limited to the facial distribution these methods would be satisfactory, but if it were referred only to the teeth relief would not follow.

The superior maxillary nerve can be reached in the spheno-maxillary fossa by going in laterally through the temporal fossa. Thus all the dental branches can be intercepted. This is an extensive operation and is followed by a large scar and muscle atrophy. Its performance calls for considerable skill. Furthermore, it is wiser to have recourse to the simpler methods first, for temporary and sometimes permanent relief may follow.

The intracranial operation consists in the removal of the whole or part of the gasserian ganglion, together with one or more of the primary divisions of the trifacial nerve. It is an operation of last resort and properly so at present, because it is difficult to perform, there is a considerable mortality, and, although immediate and permanent relief from pain follows if carried out properly, unfortunate sequelæ occasionally result. The intracranial operation does not concern us here.

The following method has been devised for relief when the dental branches are the seat of pain. First, the teeth should be examined by a competent dentist, and if found to be sound they should not be extracted. A horizontal or somewhat oblique incision about one inch long should be made over the exit of the nerve from the infra-orbital foramen and carried down to the bone. The nerve should be exposed at the foramen and with care the vessels may be spared injury, for a time at least, so as to avoid obscuring the field by hemorrhage. Free the cutaneous branches for a distance and carefully isolate the main trunk. With a small chisel remove the bridge of bone which completes the foramen above and also chisel away a considerable portion of bone below the foramen without injuring the nerve. Elevate the periosteum from the facial surface of the maxilla downward and outward towards its malar process and then continue under it so as to reach the zygomatic surface. Previous to this the antrum has been opened in front. With rongeur forceps a channel should be made in the facial wall of the maxilla extending downward and outward to a point just under the malar process, and thence as far as possible on the zygomatic surface. By means of suitable retractors and properly curved rongeur forceps this procedure offers no difficulties. This channel should be from three-eighths to one-half inch wide. Thereby all dental branches are intercepted. The bony support of the alveolus is not materially weakened, the teeth are not injured, nor is any harm done the antrum. Finally the main nerve trunk should be carefully isolated to the spheno-maxillary fissure where it is severed and then as much as possible of the cutaneous distribution teased out. All hemorrhage will have ceased on completion of the operation so that the incision should be closed with a subcuticular suture. The usual edema of the cheek will follow and last about seven days.

All of this operation can be carried out by means of an incision inside the mouth which exposes the canine fossa. The technic is a little more difficult in this method, but an external scar is avoided. This plan was used in Case II for the purpose of reaching the dental nerves. There had been a previous operation in this case and the facial distribution with a portion of the main trunk had been excised, but the neuralgia persisted in these nerves.

The only claim made for this operation is that cases of neuralgia of the superior maxillary nerve, in which pain is referred to the teeth as well as to the face, can be relieved by a superficial route. The ultimate chance of recurrence may not be altered, but if freedom depends upon the amount of nerve excised the outlook is favorable. If further intervention is called for only the intracranial operation will avail much.

CASE I. A woman, fifty years of age. For two years she suffered from neuralgia of the superior maxillary nerve. Not only were all the facial branches affected but also the branches to all the teeth on one side. She was opposed to any operation and tried innumerable drugs and other measures without any lasting relief until finally the pain became so severe and persistent that she submitted willingly to operation. Most careful examination by specialists failed to show any cause in this case. The first and third divisions had never been affected, and for various reasons I did not care to approach the nerve in the spheno-maxillary fossa. I was doubtful how best to relieve the pain referred to the teeth and finally decided to remove portions of the facial and zygomatic surfaces of the maxilla. The operation was performed in the manner described above. No complications followed; relief was immediate and there has been no recurrence in a period of ten months. The scar on the face is scarcely perceptible.

CASE II. A man, forty-five years old. This patient had been operated on elsewhere for neuralgia of the superior maxillary nerve. Both the facial and dental branches were affected. He states that following this operation the pain left the face but always persisted in the region of the teeth and gums although several teeth had been extracted. The operation performed was excision of the main trunk for a distance in the orbit together with the cutaneous branches. Only a small scar was evident.

I decided that I would intercept the dental branches by incision through the mouth in the manner described. Accordingly, a horizontal incision about one inch long was made across the canine fossa at the highest part of the vestibule of the mouth. The infra-orbital foramen was sought and found not to contain any nerve tissue. After freeing the periosteum the bony wall of the maxilla was removed well on to the zygomatic surface. The incision was left open and it closed of itself in about four days without complication. Complete relief followed and patient has not been seen since his discharge from the hospital.

THE Medical College of Ohio graduated one Egyptian student this year, and two students from that country last year. The Cincinnati College of Pharmacy graduated this year two Egyptians, and there are at present four residents of that country at the Medical College of Ohio.—*Jour. Am. Med. Asso.*

"ORGANISM X," PROBABLY OF THE CORYNEBACTERIUM GROUP: ITS DIFFERENTIATION FROM B. DIPHTHERIÆ AND ALLIED ORGANISMS. ITS PATHOGENICITY IN MAN, ESPECIALLY IN BRONCHOPNEUMONIA, AND ITS RELATION TO GENERAL PARALYSIS OF THE INSANE.

BY LOUIS HOAG, M.D., BOSTON,
Pathological Laboratory, Boston Dispensary.

ARTICLE NO. 1 — INTRODUCTORY.

As this work has already consumed a long time,[1] but as still more work seems necessary before recording a final opinion, I take this occasion, omitting here its systematic study, to present briefly such data as bear more particularly upon the differentiation of this organism, besides indicating in a general way such topics as I wish to consider subsequently. I shall omit a consideration of the literature in this introductory article and shall, for the present, call the bacillus of this paper "Organism X" for convenience.

SOURCE OF DATA ON ORGANISM X.

The bacteriological data here presented comprise: (*a*) One clinical case of pulmonary infection with organism X; (*b*) a bacteriological and pathological study of 150 insane patients coming to autopsy; (*c*) a bacteriological study of 2,310 throat cultures on blood serum from 1,000 insane (these during a mild diphtheria epidemic); (*d*) comparative study on 6 sugars of acid production and coagulation in blood-serum-water-litmus-sugar media of Bacillus diphtheriæ, organism X and bacillus Hoffmanni by means of 175 observations; (*e*) comparative study on 7 sugars of acid production in broth of B. diphtheriæ, organism X, B. xerosis, B. Hoffmanni and Ruediger's bacillus, by means of 517 titrations with controls; and (*f*) a study of cultural and morphological characteristics based upon a stock of 199 pure cultures of the "diphtheroid" group, which includes:

Cultures of Organism X,	146
" " B. diphtheriæ from Danvers epidemic,	17
" " B. pseudo-diphth. (B. Hoffmanni),	4
" " B. xerosis,	3
" " B. coryzæ segmentosus,	1
" " Ruediger's organism (from Dr. Hamilton),	4
" " a media-staining pseudo-diphth. bacillus,	1
Other forms not identified, largely falling into one or other of these groups,	23
Total stock of diphtheria and diphtheroid organisms,	199

The organism I call here "Organism X" I regard as a distinct bacteriological entity; what I record deals with but one species; in short, I have temporarily designated the bacillus Organism X to avoid confusion in terms, and because as yet I have been unable to find an adequately described and unquestionably differentiated and named species which seems identical with Organism X, but eventually I shall doubtless be able to place the organism. Descriptions, etc., on Organism X are based on cultures of the bacillus, which have been studied with care with regard to morphology, cultural peculiarities, biochemical reactions and animal inoculation, and over an extended period of time. This has been absolutely necessary, because Organism X may so closely resemble in a single point (morphology or other feature) B. diphtheriæ, B. xerosis, B. Hoffmanni or B. coryzæ segmentosus as to be indistinguishable from each in a given respect.

SOURCE OF CULTURES OF ORGANISM X.

Organism X has been found and obtained in pure culture on blood serum:

From the throat,	62 times
" " lung,	48 "
" " pleural cavity (empyema),	6 "
" " larynx,	4 "
" " ear[2] (suppurative),	4 "
" " esophagus,	3 "
" " heart's blood,	3 "
" " eye,	2 "
" " stomach,	2 "
" " spleen,	2 "
" " liver,	1 time
" " kidney,	1 "
" " brain,	1 "
" " sputum,[2]	1 "
" tonsil pus,	1 "
" cancer pus,	1 "
" tuberculous glands of the neck,[3]	1 "
" tuberculous abscess,[3]	1 "
" contused and lacerated wound,[3]	1 "
" osteomyelitis,[3]	1 "

It may be said that the lung has proved the most productive region for this organism, especially as regards purity of culture; in several cases I have obtained pure cultures directly from the lung, and again many times the first culture from the lung showed a predominance of colonies of Organism X, but with those of the common organisms as well. For the internal organs and heart's blood the same may be said, — the initial cultures have sometimes shown a pure growth of Organism X, sometimes a mixed growth.

Then I have a few cases showing great growth of the bacillus in the lung and either pure or mixed growth of the same in the internal organs or heart's blood; and always, with one exception, when appearing in the throat, it was found in the lung where examination was made.

For these reasons I regard the lung as the important seat of action. But I am satisfied the normal lung at autopsy is not a likely source for cultures. Lungs showing marked bronchopneumonia, often somewhat peculiar in the gross, both

[1] My first pure culture of this organism I isolated while on service at the Danvers Insane Hospital in March, 1904; many subsequent cultures and other forms of "material" were obtained there also, and I want to thank the Superintendent, Dr. Charles W. Page, the Trustees, and my fellow physicians of the staff of the Danvers Insane Hospital for their interest and co-operation in this work, and particularly am I indebted to Dr. A. M. Barrett, pathologist to the hospital at that time.

Of others who have assisted me I desire especially to thank Dr. Theobald Smith for his aid and advice, and Burt R. Rickards, director of the Boston Board of Health Laboratory, for his many favors.

[2] During certain studies of diphtheria-like organisms in sputum which are in progress under Mr. B. R. Richards, he has stated to me that among others he has isolated organisms from the sources indicated which respond to many of the tests and are probably identical with "Organism X."

[3] The above four cultures are the only ones appearing above not isolated by me; they were sent to me through the kindness of Dr. D. H. Bergey, of the University of Pennsylvania, under the name of "Bacterium Pseudo-diphtheriticum." They have been proved by me to be identical with Organism X; therefore I interpolate them here. See table.

early and late, with associated gangrene, have in all cases yielded the most positive results, and in such the internal organs or heart's blood were sometimes found to yield cultures, not infrequently pure, of this organism. Suppurations have yielded good growths of the organism also.

It has been found associated in the same case, the same site and culture with many common pathogenic and saprophytic bacteria; also with B. diphtheriæ; one such case is that from which culture No. 1 (B. diphtheriæ) and No. 2 ("Organism X") were isolated by me from a throat in 1904.

I have found Organism X at autopsy both in the general paralytic and in those presenting no definite symptoms of general paralysis.

MORPHOLOGY ON BLOOD SERUM OF ORGANISM.[4]

Very variable as to size and type. Commonly a small bacillus, rarely showing suggestion of rudimentary branches like B. diphtheriæ. Organism X, in culture, does not usually reach the average size of B. diphtheriæ. Small types are sometimes much smaller than B. Hoffmanni and often coccoid. Large types as large as medium-sized B. diphtheriæ. Shape: straight rods, slightly curved rods, conical like B. Hoffmanni, or coccoid. Involution types common, smaller than similar B. diphtheriæ types, but may be ten or twenty times the volume of their fellows, often "pear," "club" or huge "coccoid" in form. Arrangement either strictly palisade or in open "V" or "jackstraw," the latter less marked than with B. diphtheriæ. Relative dimensions like typical but diminutive diphtheria bacilli or often more thick and short. Granulation variable; this runs by strains very persistently, some strains mostly of small bipolar bacilli, others practically free of granules. A conspicuous type has well-defined large (relatively) bipolar and body granules, or with a single body or polar granule; body often very pale, in marked contrast with granule or granules. Barred or closely granular and even streptococcoid types are not rare.

STAINING.

Young individuals stain well with common stains. Old forms paler than corresponding B. diphtheriæ types. Here again certain strain peculiarity exists. Stains by Gram usually. Some strains are very pale with Gram, however. Involution types retain Gram better; they may be the only individuals in a "field" which unquestionably are Gram-stained when a counter stain is used. Granular types stain like B. diphtheriæ by Neisser's method; granules are usually smaller, however.

Non-capsulated; sometimes a non-staining interval between the sides of adjacent bodies in closely packed "fields" is seen.

No spores have been seen.

Motion: Non-motile, sometimes exhibits active Brownian oscillation, however.

[4] Morphology in tissues here omitted, to be treated in subsequent article.

The organism is an aërobe.

No gas production observed on glucose or saccharose broth in fermentation tube.

GROWTH.

Blood serum: More moist, more creamy and rapid in growth than B. diphtheriæ. Under good conditions of growth on blood serum most strains show, after a few days, a decided pale salmon pink tint; when old, often faint buff. Rarely, under bad conditions of growth, a yellow or a buff. The salmon pink is sometimes pronounced and is common in vigorous cultures. Media not usually stained until growth is very old.

On potato the faint salmon pink or salmon buff is readily seen.

Agar: More rapid than B. diphtheriæ and more moist, usually gray, sometimes dirty gray, and sometimes very faintly salmon tinted.

Gelatin not liquefied. Growth slow; very fine, disseminated, spherical, in depths. Surface growth dry, yellowish, elevated.

Broth: Grows well in plain or sugar broth. Marked turbidity with or without pellicle or marginal ring growth; usually the latter is present.

In glucose broth, produces marked acid formation as intense as is the case with B. diphtheriæ.

PATHOGENESIS.

Commonly non-pathogenic in the usual sense of the term to guinea-pigs, rabbits and white rats in ordinary doses. I have seen, however, decided local purulent infiltrations follow subcutaneous inoculations of the organism in guinea-pigs, in two cases followed by death. From such, "Organism X" has been recovered apparently in pure culture from the local lesion and a neighboring lymph node. I speak guardedly on this subject, as it requires further investigation.

DIFFERENTIATION OF ORGANISM X.

As the bacillus closely resembles B. xerosis, B. diphtheriæ, B. Hoffmanni and B. coryzæ segmentosus, its differentiation is somewhat difficult. In 1904 I differentiated the organism in question from B. diphtheriæ by means of serum-water-sugar-media of Hiss. I found the same characteristics to be shown much better by direct titration of sugar broths, a method recommended to me by Dr. Theobald Smith. Therefore I offer in tabular form my results with this method on the differentiation of Organism X from B. diphtheriæ, B. xerosis, B. Hoffmanni and the organism of Ruediger.

The sugar broth used for acid production in the table below contained .95% of sugar in a bouillon made up with Liebig's meat extract. One half cubic centimeter of a 20% solution of each of the following sugars — dextrose, saccharose, lactose, maltose, dextrin, mannite and inulin — was placed in sterile test tubes and sterilized by steaming sixteen minutes. To this 10 cc. of a filtered sterile sugar-free broth (rendered so by a growth of "bird colon" bacillus at 37.5° C. for eighteen hours) was added to every tube already containing

FERMENTATION TABLE SHOWING ACID PRODUCTION IN 84 HOURS AT 37.5° C. ON VARIOUS .95% SUGAR BROTHS OF "ORGANISM X," BACILLUS DIPHTHERIÆ, BACCILLUS XEROSIS, BACILLUS PSEUDO-DIPHTHERIÆ (HOFFMANN'S BACILLUS), RUEDIGER'S BACILLUS, AND OTHERS.

Figures indicate acidity in % "normal" acid or alkali of the several inoculated suger broths under appropriate columns. Initial reaction of media .6% +. Sign + means acid; sign — means alkaline.

	Private Culture Number	Source	.95% Glucose Broth	.95% Saccharose Broth	.95% Lactose Broth	.95% Maltose Broth	.95% Dextrin Broth	.95% Mannite Broth	.95% Inulin Broth

‡ Contaminated.
§ Contaminated. Earlier titration figures of culture No. 95 ran very close on saccharose to those produced by No. 108 on the same sugar.
¶ = No growths, broth absolutely clear. (Such are useful as controls, as conditions of growth, titration, etc., have been exactly the same as for inoculated cultures.)

sterile sugar solution. The tubed media were at once steamed in an "Arnold" for sixteen minutes, and after remaining for a period of fourteen hours at about 22° C., they received a final steaming for sixteen minutes. They were planted within two days, and all tubes were subjected to the same conditions of growth.

After eighty-four hours at 37.5° C. the cultures were steamed in an Arnold for sixteen minutes in convenient lots and rapidly titrated without agitation after the usual method in volumetric work, except that the above steaming was substituted for boiling. Indicator, Phenolphthalein. Initial reaction of all media .6 +.

Four of the cultures of B. diphtheriæ appearing in the table were obtained from patients of the institution during a mild epidemic of diphtheria there. Diphtheria bacillus culture No. 108 was obtained in nearly pure culture from the eye of a patient exhibiting marked local clinical signs of xerosis conjunctivæ, while previously and subsequently the eye yielded abundant cultures of true B. xerosis; No. 2131 is one of these.

FERMENTATION TABLE SHOWING ACID PRODUCTION IN EIGHTY-FOUR HOURS AT 37.5° C. ON VARIOUS .95% SUGAR BROTHS, OF "ORGANISM X," BACILLUS DIPHTHERIÆ, BACILLUS XEROSIS, BACILLUS PSEUDO-DIPHTHERIÆ (HOFFMANN'S BACILLUS), RUEDIGER'S BACILLUS AND OTHERS.

The table needs no explanation; bacillus Hoffmanni I use as synonymous with the term "pseudo-diphtheria bacillus." Of the B. xerosis cultures, 2131 has been referred to. It is well, however, to state that it always gave the dry, granular, clinging and friable surface growth on solid media which is so typical of B. xerosis; the same characteristic was shown even in the water of condensation and liquid media. Culture "Bergey No. 7," which was also typical in all respects, was obtained through the courtesy of Dr. Bergey. Of the cultures of B. Hoffmanni, two, Nos. 131 and 27, were not absolutely typical but probably they are correctly placed. "Ruediger 4" is one of Dr. Ruediger's organisms sent me by Dr. A. Hamilton.

Analysis of the table shows marked differences in the groups included. Organism X ferments glucose and saccharose rapidly and to the same degree, each reaching in eighty-four hours anacidity of from 4.+ to 5.+. On maltose inoculated with Organism X the medium rises to 3. or 4. acid; little effect on the other sugars is produced by "Organism X."

B. diphtheriæ produces in eighty-four hours from 4. to 5. acid on glucose and maltose broth, also rises to 2. or 3. acid on dextrine broth, but shows no ability to ferment the other sugars to practical degree.

B. xerosis rises in this time to about 3.4 acid on glucose and about 3.+ on maltose, but fails to produce acid on the other sugars, including saccharose.

B. Hoffmanni and Ruediger's bacillus fail to ferment even glucose.

"Organism X" is then clearly differentiated from B. diphtheriæ by its ability to ferment saccharose with just as much ease as it ferments glucose, while B. diphtheriæ, B. xerosis, B. Hoffmanni and the bacillus of Ruediger are incapable of attacking saccharose to any marked degree. I therefore regard the differentiation of Organism X from these organisms as demonstrated.

Another organism closely resembling in morphology, etc., "Organism X" is B. coryzæ segmentosus. This organism (culture "Reddington") failed to grow satisfactorily in the plantings for the table already presented, but can still, I believe, be distinguished without uncertainty from "Organism X." "Organism X" is a hardy organism growing much better and faster than B. coryzæ segmentosus, which grows slowly with much smaller, less conspicuous colonies, which die out readily if not watched. B. coryzæ segmentosus is said to produce acid on saccharose, to less degree, however, than Organism X, and it should not, I think, be mistaken for the latter.

CONCLUSION.

"Organism X" resembles closely certain members of the corynebacterium group. Having failed thus far to more satisfactorily identify this organism, I offer, omitting here lesser peculiarities, for the organism temporarily designated "Organism X," the following major differential characteristics: (1) "Organism X" ferments rapidly and to like degree both glucose and saccharose broth (.95% sugar broth as prepared by me, rises from .6+ to 4.+ to 5.+ in either sugar in eighty-four hours at 37.5° C.). (2) Commonly under good conditions of growth on coagulated blood serum of about .5+, if not subjected to conditions inimical to pigment formation in general, "Organism X" produces a pigment of a faint salmon pink color which does not stain the media until after weeks or months. This appears in two to four days under favorable conditions. In very old cultures the pink is replaced by buff. Very rarely yellow is produced, but only after the salmon pink has been seen in previous generations for months, and then under unfavorable conditions. The tendency of transplants from such cultures, if started under good conditions, is to regain the power of producing a faint salmon-colored pigment.

The above characteristics differentiate "Organism X" from B. diphtheriæ, B. xerosis, B. pseudo-diphtheriæ (B. Hoffmanni), B. coryzæ segmentosus and from Ruediger's bacillus.

"Organism X" has been found by me a number of times at autopsy as well as during life, both in pure culture and mixed, in various pathological lesions and also when not associated with local disease. It has been found conspicuously in the bronchopneumonic lung in the insane, both in general paralytics and in non-general paralytics. It has been found in the internal organs and heart's blood at autopsy, but in such it has occurred in great numbers in the bronchopneumonic lung and associated empyema of the same case, when the latter complication existed. It has been found during life in pure culture in sputum from a

patient who showed such clinical signs as are consistent with the common post-mortem findings of other cases; when such clinical signs of purulent bronchitis and bronchopneumonia ceased, the common flora of the mouth could alone be seen in cultures, and "Organism X" appeared to be absent in the little mucus that could be raised from the upper air passages by coughing and gagging. I have found it in suppurating conditions elsewhere than in the respiration system.

Therefore I regard Organism X as a factor in disease, especially as at this time so much is heard of the rôle of "diphtheroids" in this and that condition. It is my desire to present later some evidence bearing on the rôle of Organism X in man, particularly its significance in bronchopneumonia and its occurrence in the general paralytic. Likewise, after considering the literature of diphtheria-like organisms, etc., I hope to offer some statistics on the "diphtheroids" in the throats of the insane.

PAINLESS LABOR. REPORT OF A CASE DUE TO A DESTRUCTIVE LESION OF THE SPINAL CORD.*

BY E. W. TAYLOR, M.D., BOSTON.

CASES of painless labor, due to lesions of the central nervous system, are sufficiently unusual to warrant report. Such cases occur but seldom either in the experience of obstetricians or pathologists, and, therefore, may be regarded as of theoretical rather than practical interest. As a matter of fact, gross destructive lesions of the spinal cord during pregnancy serve as a physiological experiment, the significance of which should not be overlooked.

The case which has suggested the presentation of this subject before this society has already been reported at length in its various clinical and pathological details.[1] In this report the course and termination of pregnancy were alluded to as incidents in the process which was more particularly under consideration. I shall, therefore, not attempt to give the history of the case again in detail, except so far as it relates to the matters now under consideration.

The patient was a woman of twenty-four whom I first saw toward the end of her first pregnancy. She was at that time suffering from a beginning paralysis of the legs, together with sensory and sphincteric disorder, which within a few days developed into a complete motor and sensory paraplegia extending to a point about midway between the umbilicus and the pubes. The evidence from the clinical signs was conclusive that there was a complete transverse destructive lesion of the spinal cord involving the entire lumbar region. Under these conditions of complete motor and sensory paralysis of the lower extremities the baby was born.

Dr. J. C. Hubbard was in charge of the patient at this time, and up to Jan. 13 had noticed nothing exceptional in the course of the pregnancy. The severe character of the underlying lesion of the central nervous system overshadowed the obstetrical condition. On Jan. 13 a routine examination by Dr. Hubbard showed definite uterine contractions as felt through the abdominal wall. No vaginal examination was made. The patient was conscious of these contractions, but made absolutely no complaint of pain and evidently experienced none. The fetal membranes had ruptured during the night. Dr. Hubbard expressed the opinion that labor was probably beginning, but did not feel that the situation was sufficiently urgent to demand his remaining with the patient. When he returned, about three hours later, the head was on the perineum, labor having been accomplished up to this point absolutely without pain and practically without the consciousness of the patient. The uterine contractions had evidently been adequate up to this time, though probably somewhat lacking in force. The abdominal muscles, so far as ascertained, took no part in the process. There was no evidence that further progress would be made and delivery of a healthy, ordinary sized girl baby was effected without difficulty through the application of forceps. The perineum was torn and was at once sewed up without the slightest evidence of pain. There was no post-partum hemorrhage; the uterus contracted in perfectly normal fashion and without further incident. The entire labor had, therefore, been accomplished absolutely without pain, and the birth of the baby was merely an incident in the day, of small significance in comparison with the pain and distress caused by the underlying disease. There was some slight complaint when the placenta was expressed by the hand on the abdomen. The convalescence from labor was entirely uneventful, even the perineal wound healing without complication in spite of the complete anesthesia of the part and the urinary incontinence. The baby was not nursed. Dr. Hubbard has called my attention to the following points of special interest in the labor: first, its painless character; second, the absence of any distinctive use of the auxiliary muscles during the second stage; and third, the satisfactorily firm contractions of the uterus after delivery.

The patient died March 25, the paralysis of the legs remaining complete and the entire illness associated with much pain unexplained during life. The autopsy showed a completely destructive, sarcomatous tumor of the whole lumbar and sacral region of the cord, thence extending upward on its dorsal surface into the cervical region. The details of pathological findings are given at length in the paper to which I have already referred.

I wish now merely to call attention to the points which are of particular interest from an obstetrical standpoint, and especially to consider the following matters: first, the conditions under which painless labor may occur; second, the relation of the accessory abdominal muscles to the pains of labor; third, the general innervation of the uterus.

I. Olshausen[2] has pointed out that painless labor may occur in placenta previa with succulent soft parts, and also calls attention to the fact that under very rare conditions a labor may be wholly painless in normal persons. In this connection a recent paper by Wolff is of importance. Wolff[3] reports the case of a primipara of twenty-eight, who had no pain whatever in spite of normal contractions of the uterus, and likewise made no use

* Read before the Obstetrical Society of Boston, April 23, 1907.

[1] BOST. MED. AND SURG. JOUR., 1907, clvi, 161.

[3] Bruno Wolff: Ueber Schmerzlose Geburtswehen. Arch. für Gynäk., 1906, lxxxvii, 402.

of the accessory abdominal muscles in the efforts to expel the fetus. The patient was rather exhausted during the labor, but had no clouding of the mind. The pulse and temperature remained normal, and no sign whatever was found of disordered sensibility or of any other nervous derangement. There was no indication of hysteria. As the labor progressed there was no pain, but it was finally necessary to complete the birth artificially, because of weakening contractions. During this operation an anesthetic was used. Delivery was followed by some hemorrhage from the atonic uterus, but convalescence progressed normally. The labor had continued over a period of two days and the statement is made that only at the beginning were very slight pains felt. Subsequent examination of the nervous system again showed no abnormality whatsoever. The patient remembered all the events of the labor. At the beginning of the labor a small dose of morphine and chloral was given, but it was regarded as wholly insufficient to lead to a deadening of the pain to the extent observed. Wolff also refers to seven other similar cases, both primiparous and multiparous, presenting varied clinical pictures.

Such cases are, however, extraordinarily rare, especially in primiparous women. It is no doubt a sufficiently common experience that in multiparæ labor is unassociated with long-continued or severe pain. Birth in these cases is no doubt often effected by relatively few uterine contractions, but such contractions, few as they may be, are in the vast majority of cases accompanied by distinct and unmistakable labor pains. The question which chiefly interests us now is not the ease of birth in any given instance, but its painless character, when the conditions for pain are present.

The disorders of the nervous system in which painless labor occurs are essentially those in which the sensory conduction is interfered with. It is possible, for example, that a labor may be painless as a result of hysteria, in which, together with sensory disorders, a paralysis of the legs may be present simulating a structural lesion. The usual non-involvement of the sphincters in hysteria is a valuable differential point. Leaving aside various cerebral disorders, associated with disturbances or loss of consciousness, the more frequent causes of painless labor are to be found in destructive lesions of the spinal cord, involving the lumbar region or lying anywhere in the cord above. Such lesions are usually of the character of myelitis, using that term in its broad sense. Instances, for example, have been described through compression by means of tuberculosis or other external agencies. Cases of painless labor associated with tabes dorsalis are naturally explained by the involvement of the sensory tracts, but are of less interest from the physiological standpoint, inasmuch as the motor mechanism remains undisturbed. In spite of the fact that there are a number of conditions in which painless labor may occur, the cases are still extremely few in which adequate reports have been made. In 1904 Windscheid [4] collected the cases associated with myelitis and reported one of his own, which was briefly as follows: A woman, forty-three years, the mother of fifteen children, was nine months pregnant with the sixteenth. Following a fall on the buttocks there was gradual loss of power in the legs, accompanied by sensory disorders and urinary incontinence. When examined she was emaciated and completely paraplegic, except for some movement of the two great toes. There was paresis of the abdominal muscles and anesthesia up to the level of the umbilicus. Reflexes, both deep and superficial, were increased. Sepsis developed and the birth took place four days after without pain, or use of the accessory abdominal muscles, with great ease, and without knowledge of the labor on the part of the mother. She died of sepsis three days after the birth of the child. This case is evidently not a particularly striking one, first, on account of the great number of children she had had; secondly, on account of the supervening sepsis, with presumable rise of temperature and possible dulling of consciousness; and thirdly, because of the evident extreme illness of the patient during the period of labor. The clinical diagnosis of dorsal myelitis in this case was substantiated by the autopsy.

In this paper Windscheid refers briefly to cases reported by Boshan, Benicke, Nasse, Brachet, Renz, Wachenhusen, Schnitzer, and refers also to a dissertation of Kasbaum, in which the general subject is discussed. All of these cases were due to a destructive lesion of the cord, either by inflammatory or tuberculous processes.

So far as my study of the references has gone, I find no mention of a painless labor being produced by an invasion and consequent destruction of the cord through a tumor other than tuberculous. In our case it is evident that the labor was without pain, because of the destruction of the lumbar cord, through which unquestionably must be conveyed the fibers which transmit sensation of uterine contractions to the brain. The lesion found post-mortem, therefore, adequately and completely explains the painlessness of the labor.

II. The physiological significance of the pain associated with labor has always been, and remains, a matter of much interest. It is said that labor is the only physiological process in which pain is a normal accompaniment. It is, therefore, reasonable to suppose that pain has a certain definite significance in the process of birth. It is, however, evident that under certain circumstances, either of idiosyncrasy or of destructive lesion of the cord, birth may take place entirely without pain, and it therefore follows that pain cannot be regarded as essential to the process. Zweifel has advanced the theory that the object of the pains is to force the mother, through active inspiration, to supply her blood with oxygen in order that the child may not be asphyxiated when the supply of oxygen is of necessity cut off during uterine contractions. This theory evidently cannot apply to all cases, inasmuch as it has not been

[4] F. Windscheid: Ueber Entbindung bei Myelitis. Arch. für Gynäk., 1904, lxxii, 360.

shown that painless labor is fatal to the child. It is certainly not to be regarded, therefore, as a wholly adequate explanation, although it may be in a measure true. In an important paper, written in 1900, Kreis[5] reported six cases of medullary narcosis, in which labor was performed absolutely without pain and without interference with the uterine contractions. The interesting fact was, however, observed that the accessory abdominal muscles did not spontaneously contract during the progress of labor. It was also observed that a request on the part of the physician to use the abdominal muscles could easily be complied with by the patient with the usual effect. In other words, involuntary or reflex contractions of the abdominal muscles were not aroused when no pain was felt, but could be voluntarily stimulated by an act of the will. From this it follows, apparently, that pain and the action of the abdominal muscles are closely allied and that under ordinary circumstances pain is necessary to bring about the proper action of these muscles in the expulsive effort. Müller also reports thirty-two cases of adrenalin cocaine spinal anesthesia from the Greifswald clinic. In only one of these were the abdominal muscles used involuntarily, corresponding with the view set forth by Kreis. Wolff also in the paper to which we have already alluded assents to the correctness of the foregoing observation, but goes a step further on the positive side and asserts that pain is a necessary stimulus to regular contractions of the abdominal muscles, a fact first proved by the study of painless labor, whether artificially produced by spinal anesthesia or due to various pathological lesions. According to this view, therefore, the physiological significance of pain is to provide a regulatory mechanism for the action of the abdominal muscles. There is evidence to show that pains in the lower animals have a function similar to that in man. In the case which Dr. Hubbard and I have had an opportunity to observe, the labor progressed, as I have before stated, without pain. There was also no noticeable action of the abdominal muscles, although they could not have been paralyzed by the existing lesion during the progress of labor, which bears out the hypothesis to which I have just referred. In general, therefore, from this point of view, the pain of labor is to be regarded as of physiological importance in regulating the action of the accessory abdominal muscles in the act of birth. Pain is certainly not essential to effective contractions of the uterus.

III. The final question of the relation of the uterine nerve supply to the spinal cord, brain and sympathetic systems is also a matter of much interest. Budge, quoted by v. Hösslin,[6] regards the chief centers for the uterus as lying in the cerebellum, oblongata and one at the height of the fourth lumbar vertebra through which uterine movements are aroused. Similar movements may be aroused by the stimulation of the genito-spinal center at the height of the fifth lumbar segment. In general, with various divergencies in detail, observers have found centers in the cord, oblongata and in various sympathetic plexuses. Experiments have, however, shown more and more definitely the practical independence of the uterus from its central connections. Resection of the dorso-lumbar cord (Goltz) has not interfered with the birth of normal pups. Destruction of the lumbar cord itself has also not prevented normal birth. Further experiments have demonstrated that uterine contractions will take place when the uterus is separated from spinal or sympathetic tracts. Kurdinowski, for example, showed that a wholly separated rabbit uterus is capable of contracting in normal fashion. Still more extraordinary is a case[7] recently reported by Schmorl, which was briefly as follows: A woman, thirty-three years old, while pregnant, developed a rapidly growing myoma of the uterus, for which operation was attempted. It was, however, found that the myoma could not be successfully removed on account of excessive hemorrhage, and a complete hysterectomy was done. After removal of the uterus, on examination, it was observed that the internal os was slightly patent. In half an hour thereafter the size of the os increased to the size of a five-mark piece, and at the end of two hours a fetus, estimated at about the third month, was born. During this period of "labor," slow contractions of the uterine muscle were observed. After the birth of this fetus, the birth of a second began, but the uterine contractions were not sufficient for its expulsion. This remarkable case is a further striking proof that uterine contractions are possible after complete separation from the central nervous mechanism. It is also of interest in connection with certain cases reported of births after death.

The general conclusion is, therefore, necessitated that the uterus of mammals, even after the cutting off of the cord and ganglia lying in the hypogastric plexus, is capable of rhythmical contraction, but it appears that such contractions are somewhat less forcible than when the entire nervous system is intact. The brain is to be regarded simply as a regulatory mechanism. Armand Routh (quoted by v. Hösslin) has summarized our existing knowledge of the entire matter, in general, as follows:

1. Birth is partly automatic and partly reflex.

2. Direct connection with the brain is not essential for co-ordination of uterine action, although the brain appears to have influence on the pains in so far as it contributes to their regularity.

3. Direct connection between the uterus and lumbar enlargement, through the agency of sympathetic ganglia between the first and third lumbar vertebræ is apparently necessary for the regular contraction and retraction of the uterus as seen under normal conditions.

4. The uterus is apparently capable of expelling its contents provided the genital canal is re-

[7] Schmorl: Centralbl. für Gynäk., 1906, xxx, 917.

laxed when totally cut off from the spinal cord, but its contractions are more likely to be irregular and incomplete.

The observation of the case reported briefly in this paper serves to substantiate many of the points to which allusion has been made, and demonstrates from the standpoint of a unique pathological lesion that uterine contractions may occur without pain; that the fetus may be carried far on its way, if not wholly expelled, by a uterus separated from its central connections and without the aid of the abdominal muscles; and that its final contraction after the expulsion of the placenta may be complete and satisfactory, precluding the likelihood of post-partum hemorrhage.

Clinical Department.

"A CASE OF CHRONIC OTITIS MEDIA, HEMORRHAGE INTO THE EXTERNAL AUDITORY CANAL, PERFORATION OF THE WALL OF PHARYNX, WITH FATAL HEMORRHAGE FROM THE JUGULAR VEIN.*

BY FREDERICK L. JACK, M.D., BOSTON,
AND
FREDERICK H. VERHOEFF, M.D., BOSTON.

J. O., two and one-half years old, was first seen at the Massachusetts Charitable Eye and Ear Infirmary on Jan. 8, 1907, when the following history was obtained. The patient had never had any of the diseases of childhood, or any ear trouble prior to the present attack. For two weeks she had been fretful and evidently in pain. A discharge of pus from the right ear had been noticed for several days, and a swelling postaural for nearly a week. Considerable coagulated blood was found in the right meatus. Over the mastoid tip, extending about one inch below and one and one-half inches posteriorly, was a large fluctuating swelling about the size of a tangerine, tender on pressure. About two hours following admission to the ward the child was taken with severe hemorrhage from the mouth and nose. When the House Surgeon arrived the child was not breathing and was exsanguinated. Clots were found in the mouth and nares, with signs of vomitus on clothing. Adrenalin was given subcutaneously and normal salt solution, together with artificial respiration, but without avail.

Autopsy by Dr. Verhoeff, nineteen hours after death, head only. Body that of a fairly nourished female child. Slight rigor mortis. Lividity of dependent parts. Both nostrils and right external auditory canal are filled with clotted blood. Below and slightly behind the meatus there is a swelling about the size of an olive, over which the skin shows ecchymosis. Meninges and brain are normal, no evidences of tuberculosis. The venous sinuses are free, including the right lateral sinus and bulb. The whole temporal bone, with a large amount of the soft tissues beneath it, including a portion of the wall of the pharynx, removed and hardened forty-eight hours in 10% formalin. A stream of water can be forced through the carotid canal without any of it finding its way into the tympanum. The soft tissues beneath the bone, which contain the carotid artery and jugular vein, are infiltrated with blood from a large hemorrhagic extravasation. This is in communication with the pharynx a short distance below the mouth of the Eustachian tube. It also extends outward to the angle of the jaw, undermines the subcutaneous tissue, forms the swelling already mentioned and communicates with the lumen of the external auditory canal at the bony margin of the latter. The tympanic membrane is now intact, but is retracted and united to the promontory, evidently as the result of an old perforation. The tympanic cavity and Eustachian tube contain a large amount of exudate, but are free from blood. The ossicles are *in situ*. Attached to the wall of the tympanum are several small polyps. The attic and mastoid cells are filled with exudate, but the bony tissue is apparently not necrotic. The lining of the carotid artery, in its nearest vicinity to the tympanum and Eustachian tube, is smooth and intact.

Histological examination (Decalcification in 5% nitric acid, embedding in celloidin): The wall of the external auditory canal shows a marked inflammatory reaction and is giving off an exudation of pus cells. The tympanum shows the appearance characteristic of chronic suppurative otitis media. The submucosa is markedly infiltrated with chronic inflammatory cells, and the free exudate consists chiefly of serum and pus cells. The lining epithelium is comparatively normal. The polyps are found to consist of edematous connective tissue only slightly infiltrated with inflammatory cells. The air spaces leading out from the tympanic cavity are filled with seropurulent exudate. The medullary spaces of the surrounding bone show an infiltration with chronic inflammatory cells, among which plasma cells largely predominate, and occasional foci of pus cells. The internal ear is normal. The carotid artery itself is normal, but its sheath shows a marked chronic inflammatory reaction which extends as far as the first bend in the bony canal, but which is most marked at the entrance of the latter. The sheath of the artery for a short distance is also infiltrated with blood which has forced its way from the large hemorrhage beneath the temporal bone. The soft tissues in which this hemorrhage has taken place are involved in a formation of granulation tissue in which occur large areas of pus cells. The wall of the jugular vein, which passes through this abscess, is completely necrotic, lined with purulent thrombi and in places perforated. Higher up, where the vein is in relation with the bone, its wall is normal. Sections of the abscess beneath the temporal bone, stained by the Gram method, show numerous streptococci occurring in short chains and pairs. No other bacteria are to be seen.

Diagnosis. — Chronic suppurative otitis media, abscess beneath temporal bone, due to streptococcus pyogenes. Perforation of internal jugular vein. Infected hematoma. Hemorrhage into external auditory canal. Perforation of the wall of the pharynx, with fatal hemorrhage from internal jugular vein.

A STRANGE REASON FOR PERSISTENT ABDOMINAL PAIN. INTESTINAL ADHESIONS CAUSED BY A PIN WHICH HAD PENETRATED THE UMBILICUS WITHOUT THE KNOWLEDGE OF THE PATIENT.

BY FARRAR COBB, M.D., BOSTON,

Assistant Visiting Surgeon to the Massachusetts General Hospital.

IT is recognized that intestinal adhesions, with or without abscess formation, may be caused by the migration from the stomach or intestines of sharp foreign bodies, such as pins, needles or fish bones, which have been swallowed. Occasionally such cases have been reported. The case detailed here is probably unique because of the location and method of entrance of the pin and the entire ignorance of the patient in regard in it. Because of the very unusual condition found at operation, it is thought worth while to report it.

M. H., single, nineteen years old, entered the West Surgical Service of the Massachusetts General Hospital on Oct. 8, 1902. Dr. Beach, the senior surgeon of the service, very kindly turned the case over to me. For two weeks she had been under observation in the Out-Patient Department and was recommended to the wards for operation because of a suspected abdominal neoplasm or tubercular peritonitis. The family history was unimportant. She had always been in good health until the onset of the present trouble about three months ago. Catamenia began at sixteen years, at first profuse, but in the last two years scanty and accompanied for one day by much pelvic pain, requiring her to go to bed. There had been considerable irregularity, but none for several months. Three months before entrance, without known cause, she began to be easily tired and to have constant pain in the abdomen, most severe in the region of the umbilicus and in the left hypochondrium; it was sometimes sharp and darting and ran into the pelvis and up to the region of the left breast. This pain had been slowly increasing in severity, but the patient had done her usual housework until two weeks ago, when it became so intense that she could not stand. From the beginning her appetite had been poor and there had been some nausea, but no vomiting. She had slept poorly and had had more or less headache. She noticed that she was compelled to pass urine frequently, as often as once an hour during the day and more than twice during the night, and that for a few weeks before entrance the act of urination had been painful. The bowels had moved daily and the movements were dark in color; she had noticed no blood. She thought she had lost weight, but did not know how much. She was very anxious to be relieved from pain, which prevented her from earning her living as housemaid.

Examination showed a well-developed and nourished young woman. Nothing abnormal in the chest. Urine normal. Leucocyte count, 18,000. Hymen present. Uterus small, anteflexed, movable. Left kidney palpable. Palpation of the abdomen developed tenderness at the umbilicus, most marked on the patient's left and running into the left hypochondrium, with slight muscle spasm. Nothing abnormal in the appearance of the umbilicus was noted. The patient was kept in bed under observation for four days, during which time the evening temperature was 100° F. daily. Pulse and respiration were normal. During this time she complained constantly of pain in the region of the umbilicus, with nausea, but nothing abnormal was found upon examination except the tenderness mentioned above. Operation was determined upon because of the pain, which was manifestly severe at times. No certain diagnosis of the cause for the pain seemed possible.

The case was operated upon by me on Oct. 13. The anesthesia was nitrous oxide gas followed by ether. Bimanual examination after the patient was under ether revealed nothing abnormal in the pelvis save marked anteflexion of the uterus. After dilating and curetting the uterus, to correct to a certain degree the anteflexion, the patient was placed in the Trendelenberg position and the abdomen opened in the median line for the purpose of exploration. Upon opening the peritoneum the following conditions were found: The urachus was much larger than usual, fully the size of a pencil. The bladder seemed normal in size, but apparently was held partially out of the pelvic cavity by the large urachus. For the space of one to one and one-half inches above and below the umbilicus the omentum was firmly adherent to the anterior parietes and to the small intestine; the omental adhesions surrounded the urachus and bound it and the small intestine firmly against the abdominal wall in the umbilical region. Palpation of the omental adhesions detected a hard mass the size of a large English walnut buried in the adhesions just under the umbilicus and in the center of this a sharp object like a pin or a needle was felt. The omental adhesions were tied off with catgut. After separating the intestine with some difficulty the urachus, which was found to be patent, was tied off and excised. The sharp object was discovered to be a common pin which had penetrated the abdominal cavity by transfixing the umbilicus. For the sake of showing the pin *in situ*, as well as adopting the best method of removal of the infiltrated area (see illustration), the umbilicus, with a moderate amount of neighboring tissue, was excised, after which the abdominal excision was closed in layers. Examination of the excised tissues showed that the pin had entered at the umbilicus and had become buried in omental adhesions, but no point of entrance on the external skin could be found. The urachus in the inflammatory mass excised was practically obliterated. In all probability the urachus had been patent up to the skin

covering the umbilicus previous to the reaction caused by the pin.

The patient made an uneventful recovery and was seen by me three years after the operation, when she reported herself as in good health, with no abdominal pain and regular catamenia. She occasionally was bothered by frequency of micturition, but not nearly so much as before the operation.

In the illustration is shown in a semi-diagrammatic way the condition found at operation. The patient at all times denied all knowledge of how the pin gained entrance into her abdominal cavity, but on close questioning after the operation she remembered that she had fallen down a flight of stairs shortly before the onset of the abdominal pain. The fall was a bad one and she suffered from painful bruises. It is possible that at this time a pin in her clothing may have been forced through the tissues of the umbilicus, which were thinner than normal by reason of the patent urachus, and the pain of her other injuries prevented her noticing the minor wound. It is interesting to note the frequency of micturition associated with the abdominal pain. This may have been caused by a certain amount of shortening and contraction of the patent urachus due to its involvement in the mass of adhesions; on the other hand, it may have been a purely reflex nervous manifestation.

Medical Progress.

PROGRESS IN PEDIATRICS.

BY THOMAS MORGAN ROTCH, M.D., BOSTON,
AND
JOHN LOVETT MORSE, A.M., M.D., BOSTON.

STENOSIS OF THE PYLORUS IN INFANCY.

(Concluded from Vol. clvi, No. 26, p. 854.)

It is evident from these cases that the majority of authors disagree with *Heubner* as to the best method of feeding these cases. They almost all agree that it is better to give small amounts often rather than large amounts at longer intervals. They also almost unanimously favor lavage. Most of them believe that breast milk is the best food in this condition, although some believe in giving it diluted. Some give alkalies, believing that the condition is due to hyperacidity. Marx used them in one of his cases in which the acidity was high with good results, but did not use them in another in which the acidity was low. The Germans, led by Ibrahim, use poultices to the abdomen and feel that they are of considerable value. [The writers are somewhat skeptical as to the efficacy of poultices in these cases.]

Very few opinions have been expressed as to what happens when recovery occurs since Ibrahim summed up the subject in his paper. Marx, however, believes that recovery takes place largely as the result of compensatory hypertrophy of the other muscles of the stomach.

Several cases have been treated by small doses of opium before feeding, with apparently good results. These cases are as follows:—

Neild: Visible peristalsis; tumor. No improvement on bismuth and soda with breast feeding. One-sixtieth minim of tincture of opium twenty minutes a.c. Much improvement in a week. Opium stopped in five weeks. Recurrence of vomiting. Opium resumed and vomiting relieved. Dose gradually diminished. Recovery complete and lasting.

Visible peristalsis; tumor. Same diet. One-eightieth minim tincture of opium twenty minutes a.c. No improvement in a week. Then one-fortieth minim given. Marked improvement in a week. Continued to do well.

Third case doing well under same treatment also referred to.

Rob: Visible peristalsis; no tumor. No benefit from changes of food and lavage. One-eightieth minim tincture of opium twenty minutes a.c. Improvement in one week which continued. Well five months later.

Sutherland, however, gave up to seven minims daily of the liquor opii sedativus for some time without any effect on the peristalsis.

In speaking of the medical treatment of pyloric stenosis Sutherland remarks that the pylorus has two functions, — one of contraction and one of relaxation. The latter has been pretty generally overlooked. The fact that the muscular fibers are hypertrophied is no reason for assuming that only the power of contraction is retained. In fact, the hypertrophied pylorus has been seen to relax during an operation. The variation in the severity of the symptoms shows that even in marked cases it relaxes at times. The difficulty is that it does not do so enough to allow sufficient nourishment to pass through. The aim of medical treatment must be, therefore, to restore the function of relaxation of the pylorus, which has been in abeyance to the more powerful action of the constrictor muscular fibers. All sources of irritation in the stomach which may maintain pyloric spasm must be removed. It must be kept free from irritating food. Small amounts must be given at a time, in order to secure complete digestion. Lavage must be used daily for a long time, best at a time when, under normal conditions, the stomach is empty. Breast milk is the best food. Fats, in artificial foods, are likely to cause trouble. Finally, he expresses "the hope and belief that as our knowledge and experience of the medical treatment advance there will be fewer and fewer cases in which surgical intervention is called for."

Very little work has been done in most cases as to the chemistry of the gastric digestion, and what little work has been done has given varying results. It is safe to say that nothing of importance has been learned in this line.

A whole session of the Section on the Diseases of Children at the Toronto meeting of the British Medical Association, last summer, was devoted to this subject, and several valuable papers were presented, notably those by Cautley and Stiles. Many valuable points were also brought out in the discussion of these papers.

Cautley distinguishes between functional pyloric spasm and congenital hypertrophic stenosis. He says that there is a group of cases in infancy which shows a combination of symptoms which are extremely liable to give rise to an erroneous diagnosis of congenital hypertrophic stenosis and to which the name of pyloric spasm may be given. He admits that there is no absolute proof that there is spasm of the pylorus in these cases, but says that he can put forward no other plausible explanation. The main feature of this condition is severe and continued vomiting. The food is usually brought up at once, but sometimes a considerable quantity is kept down and then violently ejected. Constipation may be present. Some of his cases had visible peristalsis and dilatation of the stomach. He makes no mention, however, of tumor. He thinks that these cases prove that spasm of the pylorus is not the cause of the marked hypertrophy of the pylorus seen in congenital hypertrophic stenosis.

He has had sixteen cases of congenital hypertrophic stenosis and bases his conclusions on these cases. He believes that it is congenital in origin and that it is rarely compatible with long life. He attaches great importance to visible peristalsis and states that it may be visible only after feeding and that it is best elicited by giving a fair sized meal, by flicking the stomach wall with the finger or by applying a cold object. Dilatation depends on the duration and degree of obstruction. The absence of dilatation is not a contra-indication in early cases at a time when operative treatment gives the best results. The diagnosis is certain if the pylorus is felt. It is greatly to the detriment of the child, however, if the physician waits until he can definitely feel a tumor before he ventures to make a diagnosis.

He divides the cases into typical and mild. In the typical cases there is characteristic vomiting, constipation, wasting, visible peristalsis, dilatation of the stomach and tumor. In the mild cases the vomiting varies with the diet. If the stomach is washed out daily and a diluted food given, vomiting may be entirely absent for a week or more at a time and the infant may gain in weight. These are the cases which may get well without surgical aid. It is probable, however, that the hypertrophic stenosis of adults is due to the persistence of the infantile condition. Some may recover; others suffer from chronic gastric trouble; most die from progressive wasting. He says that although the amount of muscle may vary a little in the normal pylorus and in those who apparently suffer from spasm, it remains very small and in section roughly triangular. There are no intermediate stages between the conditions found in these and those found in hypertrophic stenosis. He believes "that Nature in her extreme anxiety to provide a sufficient pyloric sphincter has overexerted herself and produced too great a quantity of muscular tissue. There is a true hyperplasia, a simple redundancy of fetal growth." He brings forward various arguments against spasm as the cause of the hypertrophy.

In speaking of the diagnosis between spasm of the pylorus and hypertrophic stenosis, he says that in the former the vomiting is different in character, peristalsis is slight or absent, the stomach is rarely dilated, pronounced constipation is unusual, there may be diarrhea and there is no tumor. It is rare for two or more feeds to be retained and then vomited. In case of doubt the effects of medical treatment are of value. There is greater danger of pyloric spasm being diagnosed erroneously as pyloric hypertrophy than of the opposite mistake being made.

The outlook is extremely bad if treatment is purely medical even when the obstruction is incomplete. He believes in early operation and that the prognosis depends mainly upon the general condition of the infant. He believes that pyloroplasty is the best operation.

Stiles quotes Professor Cunningham at considerable length with regard to the musculature of the pyloric canal. Cunningham found great thickening of both muscular layers in the specimens which he examined. Stiles believes, therefore, that from the purely anatomical point of view the only difference between the normal pylorus and the stenosed pylorus, as met with in infants, is that in the latter the muscular coat is greatly thickened. He believes that it is a distinct pathological entity, but admits that both in the child and in the adult there is clinical evidence to support the view that cases of pure spasmodic stenosis of the pylorus do occur, and believes that the majority of the cases of infantile pyloric stenosis that have recovered without operation belong to this category. A considerable number of cases presenting the symptoms of pyloric stenosis have recovered without the aid of surgical treatment. It rests with the physician to settle whether these recoveries are cases of spasm without hypertrophy or a combination of spasm and hypertrophy, the former predominating. It is of great importance to follow up the life history of such infants as are supposed to have been cured of pyloric stenosis without operation. If they again suffer from gastric symptoms pointing to pyloric stenosis surgical treatment will take the same place in pyloric stenosis of the infant that it has taken in that in the adult.

He divides the cases of pyloric stenosis into two distinct groups, namely, the purely spasmodic without any hypertrophy, and the true congenital hypertrophic in which a varying amount of spasm or tonic contraction is superadded. The first group may be expected to get well under dietetic and medical treatment, while the latter group must assuredly die unless surgical treatment is resorted to. He does not think that the kind of operation is of much importance, the main point being to operate early. He believes that there is an intermediate group in which the hypertrophy, although present, is less marked. It is these cases which have probably led to the confusion and differ-

ence of opinion which exists among physicians regarding the pathology and treatment of infantile pyloric stenosis. He advises a diagnostic incision in all cases in which the diagnosis is doubtful and in which medical treatment is not bringing about an improvement. If the case is one of spasm without hypertrophy the physician and surgeon should together decide as to the advisability of divulsion. If the infant is young and feeble and the hypertrophy not marked he prefers divulsion. If the general condition is satisfactory and there is marked hypertrophy, the choice lies between pyloroplasty and gastro-enterostomy.

The following summary in an editorial in the *British Journal of Children's Diseases* sums up the subject very well: "The summary of the writings and observations of the past year indicates that the disease is much more common than is generally supposed; that operative treatment in wasted infants is not often successful; that cases with apparently all the symptoms of the affection do get well without operation; that great care is essential in diagnosis before accepting a diagnosis of pyloric hypertropy necessitating operation from pyloric spasm, which is curable by simpler measures." In summing up our evidence it should be said that diagnosis in any case not operated on or autopsied is open to question.

It is evident that much has yet to be learned concerning these conditions and the diagnosis between them. It is especially important to know what happens eventually to those cases which are supposed to have stenosis and recover under medical treatment. An autopsy on one of these cases dead of some other disease after a lapse of months or years will teach us a great deal. So would an autopsy under similar conditions on a case cured by operation.

Reports of Societies.

ASSOCIATION OF AMERICAN PHYSICIANS.

REPORT OF THE TWENTY-SECOND ANNUAL MEETING HELD AT WASHINGTON, D. C., MAY 7, 8 AND 9, 1907.

FIRST DAY, TUESDAY, MAY 7.

ADDRESS OF THE PRESIDENT.

Dr. F. P. Kinnicutt, New York, referred to the deaths of Dr. Jas. Stewart, of Montreal, and Drs. I. E. Atkinson and Thos. Lattimer, of Baltimore. He then gave an outline of the work to be done at the present session, saying: "The successive meetings of the Association of American Physicians have proved the wisdom of its founders. In the twenty-two years since its birth much of the best work of the laboratories and clinics of the United States and Canada has been yearly presented for the consideration, discussion and instruction of its members. Embracing, as it does, in its membership, the pure scientist in medicine, and the clinician in every field of its practice, this body has been an admirable example of the science and art of medicine walking hand in hand, the one or the other leading for the moment, but always with the willingness and desire to have its steps corrected if per chance straying from the path of truth. Such a union has given the Association its great strength. Only by such union is secure progress in medicine attainable."

THE CONNECTIONS OF THE OCCIPITAL LOBES AND THE PRESENT STATUS OF THE CEREBRAL VISUAL FUNCTIONS.

Dr. Adolph Meyer, New York, presented this paper under the following subdivisions: 1. Isolation of the geniculo-calcarine tract (2 cases). 2. Subdivision of sagittal marrows and their course. Marking of the calcarine area. 3. Degeneration of the occipital efferent path and the geniculo-calcarine tract, following degeneration of the calcarine cortex. 4. Marchi-degenerations from a small wound of the post-parietal cortex, involving the optic radiations: (1) afferent character of the external sagittal marrow; (2) efferent character of the internal sagittal marrow (contributing to the lateral part of the crus); (3) subcortical (external sagittal) fibers towards the motor area; (4) no fibers to the frontal lobe. Anatomical data for clinical co-relations.

Dr. L. F. Barker, Baltimore, said we should be grateful for this contribution to our knowledge of the association fibers which connect the primary visual centers with the adjacent and more distant centers. These studies were of the very greatest importance for diagnosis in neurology and psychology. It was only by control of clinical observations, by pathological anatomy, that we could hope for better ideas of localization and association.

CERTAIN FEATURES OF THE "NERVOUS BREAKDOWN," WITH SPECIAL REFERENCE TO TREATMENT.

Dr. James J. Putnam, Boston, in this paper studied the acute "nervous breakdown" as really typifying processes which are characteristic of more chronic neurasthenic conditions, but as affording especially good chances for observation, because the whole illness

runs its course, so to speak, under the physician's eye. The most striking example of this acute breakdown was perhaps the so-called traumatic neurosis, characterized by its period of predisposition, followed by periods of nervous shock, of apparent absence of symptoms, of gradually increasing illness, of an apparently stationary stage, of convalescence and recovery. Similar processes were of frequent occurrence as a result of non-traumatic shock, of strains during school and college life and many analogous influences, while diminutive periods of like type were frequently met with as intercurrent events in the course of chronic illnesses. The controlling influence in the causation of these states, and the controlling means of treatment, was the mental state of the patient. The essayist said that two classes of persons seemed to escape from these strains. First, those who have been prepared against such exigencies. Football players seldom suffer from such breakdowns; the same may be said of the soldier. A second kind of immunity was that possessed by persons who are broad on social lines and philosophical on ethical lines. They were guarded against a great variety of accidents. A large number of our troubles were social troubles, and this broad preparation which enables us to look upon social failure in a philosophical way gave immunity from strain. The treatment might be classed broadly as consisting of forms of re-education. The splendid method of Dr. Weir Mitchell, and the more specific method of re-education explained and worked out by Janey and others, were to be made use of; we should make patients more efficient, more philosophical and more ethical. We might not talk philosophy and ethics to patients in a technical way, yet if physicians were more trained in these departments of learning they would succeed better with this class of cases.

DR. JOHN MITCHELL, Philadelphia, asked about the more definite treatment of the early stages of acute nervous breakdown; very few neurologists, he said, see patients in this state.

DR. ADOLPH MEYER, New York, said that if we abstractly state that physicians should teach their patients philosophy and ethics, many physicians might take a rather strong misconception of the whole matter. The ethics that would be teachable and that would ultimately prevail would be the ethics and philosophy worked out of the common sense of our every-day experience.

DR. CHARLES DANA, New York, said nervous breakdown led to the development of mild types of psychoses. If the patients were put under ordinary common-sense environment they would get well in three, six or twelve months, or two years. The majority of these so-called neurasthenias were not nervous breakdowns but psychoses, and if put under proper conditions would get well, while if the strain were kept up the psychoses would become chronic.

DR. A. JACOBI, New York, examined these cases from an additional point of view; those that he had seen had almost all suffered from changes about the heart of a myocardial character. There was an active physical change, and by attending to the physical condition of the heart we could render great service to the patient.

DR. PUTNAM, in closing, said the treatment of the acute stage presented the greatest difficulty. In several traumatic cases he had found that absolute rest and encouragement had a very considerable effect. He agreed with Dr. Meyer that the whole thing should be put on the simplest and most matter-of-fact basis and believed, with Dr. Dana, that in these cases there was a psychosis. He believed that it was not a pure psychosis, but there were the physical signs. It must react upon the heart and all the viscera and even modified the galvanic conduction of the skin. He thought if philosophy is a science this was the place where it might be made effective.

THE CLINICAL STUDY OF ASPHASIA.

DR. CHARLES L. DANA, of New York, presented the results of the analysis of a series of cases of aphasia, clinically studied, aiming to secure a grouping of the aphasias as they are seen at the bedside, with a description, so that such groups might be recognized by the physician and taught to the student. The author discussed the views of Prof. Pierre Marie and said the old classification of aphasias have broken down in practice, and he offered an anatomical classification which he regarded as more practical, representing the type of aphasia upon certain charts devised by himself.

DR. M. A. STARR, of New York, thought that while the classification was not wholly a new one, it certainly had a great deal of positive merit. He was glad to have Dr. Dana put himself on record as recognizing these various types distinctly. Dr. Dana has brought forward evidence that establishes our older theories and controverts the very radical assertion of Marie, which his own experience did not support.

DR. J. C. PUTNAM, of Boston: These anatomical distinctions are very important, and I think this classification is very practical.

DR. DANA, closing: I believe that Marie has not proved that the frontal lobe of Broca's convolution has not a knowledge function.

THE PRESENCE OF INFLAMMATORY MASSES IN THE ABDOMEN SIMULATING MALIGNANT GROWTHS.

DR. E. G. JANEWAY, New York. The paper considered the existence of masses which either by palpation and ordinary examination, or by these and laparotomy, were considered malignant, but disappeared later. Two of these occured in connection with ulcer of the stomach, the others in different places in the abdomen.

DR. WM. OSLER, Oxford, England: We are indebted to Dr. Janeway for bringing this group of cases before us. They form an interesting anatomical group, which may be divided into: (1) Those associated with the gall bladder; (2) those associated with the stomach; (3) a large group of appendicular cases; and (4) cases associated with trouble in the sigmoid. I had my attention called particularly to the group of cases in which there has been a tumor mass connected with the sigmoid flexure, low in the left iliac fossa. This may be either the thickened glandulæ epiploacæ which have deceived even the elect, in cases where there has been diarrhea, dysenteric symptoms, blood, progressive emaciation and, on deep pressure, a definite nodular mass to be felt. In two cases operation showed the thickened masses, which we had supposed to be tumors, were, in reality, only the indurated glandulæ epiploacæ. In another group of cases in this region there is a thickening due to the perforation by a foreign body, usually a small spicule of some sort, or pericolic inflammation in that region. Such a condition existed in our distinguished surgical colleague, who was operated upon so happily last year and who had made up his mind that he had a carcinoma. It was only a thickened mass connected with the colon, probably largely pericolic in character.

We should, in these cases, urge early operation. While there are certain instances in which the surgeon disappoints us, yet, on the other hand, there are a great many cases in which the operation is very satisfactory and sometimes the tumor disappears apparently as the result of the opening of the abdomen.

THE ETIOLOGY OF ACUTE PANCREATITIS.

DRS. H. U. WILLIAMS and F. C. BUSH, Buffalo: Some recent cases of acute pancreatitis had been collected

with the idea that the more recent cases had been studied more carefully than those reported previously and the pathological anatomy would probably be more accurate. In the series collected gallstone occurred in only about 40% of the cases. In the cases where gallstones occur not a sufficient number occurred in the bile passages or in the diverticulum of Vater to make the authors think that the theory suggested by Opie that the association of gallstones with acute pancreatitis would explain all such cases. The authors suggested this mechanism: that the passage of stones left the opening of the diverticulum patent, so that under the pressure of the intestinal contractions the contents of the duodenum could go backward into the bile duct and pancreatic duct. They found some evidence to support this in their experiments on animals. They were not able to determine what particular constituents of the contents of the duodenum produced pancreatitis. Previous experiments and various investigators had shown that a great variety of substances injected into the pancreatic duct are capable of producing pancreatitis. By this injection of duodenal contents the authors were able to produce pancreatitis in some of the animals injected. They introduced an artifical gallstone into the common bile duct and forced it through the diverticulum by means of a probe from behind. They were then able to cause the contents of the duodenum to regurgitate under pressure in some cases and some of these cases were followed by pancreatitis, but more particularly by fat necrosis.

DR. EUGENE L. OPIE, New York: It seems to me by no means improbable that the mechanism that Dr. Williams has described might occur, that is, that a gallstone lodged in the lower end of the pancreatic bile duct might allow the penetration of duodenal contents into the pancreas, thus causing hemorrhagic pancreatitis since it is well known that a great variety of irritants so introduced produce the lesion. In the cases which I have examined in which especially large gallstones have occupied the diverticulum of Vater, the condition has been associated with chronic pancreatitis rather than acute pancreatitis. Apparently, the obstruction of the duct allows the penetration of the bacteria, though not of the duodenal contents, in sufficient quantities to produce the lesion. I am rather surprised to find that the proportion of gallstone cases in association with acute hemorrhagic pancreatitis is so small in Dr. Williams's cases. It may be due to the fact, as he suggests, that the bile passages are often neglected in the examination. Dr. Flexner has recently shown that bile salts are most efficient in causing acute pancreatic lesion and fat necrosis. He has found that the most extensive fat necrosis, and that most closely resembling the human lesion, occurs after the injection of bile salts into the pancreatic duct.

THE CALCIUM, MAGNESIUM, PHOSPHORUS AND NITROGEN BALANCES IN A CASE OF SO-CALLED PHOSPHATIC DIABETES.

DRS. L. F. BARKER and C. VOEGTLIN, Baltimore: This paper included the results of a metabolic study in a case of so-called phosphatic diabetes. A woman, who for years had suffered from dry skin, cracking of the heels and nervousness, and who had had constantly urine of high specific gravity and acidity, was placed upon Folin standard diet and the calcium, magnesium, nitrogen and phosphorous balances studied. The metabolism was abnormal; the urine on standard diet presenting high organic acidity, not due to uric acid, phosphates or lactic acid.

DR. WM. OSLER, Oxford: The chief point of interest in connection with this case is that any one of you would have said at once it was a case of diabetes: a Jewess, stout, with high specific gravity in the urine, frequent furunculosis, splitting of the fingers and heels. Repeated examinations by competent chemists, however, failed to discover any trace of sugar. She was under Van Noorden's care two or three times. She consulted me many times. I always regarded it as a case of prediabetes, expecting that at the next examination sugar would surely be found. I am exceedingly thankful that Dr. Barker had made this investigation as it is likely to turn out to be an entirely new type of disordered metabolism.

DR. ALONZO E. TAYLOR, Berkeley, Cal.: I am able to adduce a personal experiment. About two years ago I placed myself upon an ash free alcohol free diet. I was abstracting from my body each day so many grams of bases, which must have come from my muscular tissues and nerve tissues. The symptoms were at first only those of lassitude. About the sixth day I noticed a great deal of itching; then the entire muscular system became excessively sore to the touch. I lost entirely the power of sleep. At this time acidosis in the form of diacetic acid appeared. The irritability was profound. I realized that I was near the danger point and returned to normal diet. Within two or three hours of the ingestion of common salt there was a return to equilibrium of the nervous system.

DR. BARKER, closing: There is not any doubt that salts are just as important for our food as proteids, fats and carbohydrates. What Dr. Taylor has said is of the greatest importance. Such cases give us an interesting outlook for the future. It seems possible that for the neuroses, and possibly for the psychoses, we may be coming to the real organic basis.

THE RELATIONS BETWEEN DIABETES AND PREGNANCY.

DR. AUGUSTUS ESHNER, Philadelphia, said diabetes was uncommon during pregnancy in proportion as it is uncommon during the child-bearing period. Exceptionally, it had recurred during successive pregnancies. Pregnancy rarely occurred in diabetics, partly because diabetes in women is most common after the menopause, partly because of the debilitated general state of the diabetic patient and partly because of the functional derangement and the structural alteration of the generative organs. Complication of the one condition with the other usually increased the gravity of both. Often the fetus died *in utero*, or premature labor set in, the fetus dying at birth or shortly afterward. The liquor amnii had been found increased and in some instances to contain sugar. The mother sometimes died of the disease shortly after labor. In Dr. Eshner's case of diabetes the sugar disappeared from the urine with the inception of pregnancy, remaining absent until after the birth of a macerated fetus at term and reappearing shortly afterward.

EXPERIMENTAL FIBRINOUS PLEURISY.

DR. EUGENE L. OPIE, New York, read this paper, in which he concludes that sero-fibrinous pleurisy is produced by a sterile inflammatory irritant such as turpentine injected into the pleural cavity of the dog. Accumulation of fluid reaches a maximum at the end of three days and fluid has completely disappeared at the end of six days. Resolution of fibrin begins (first stage) while fluid is present and is completed (second stage) after the disappearance of the growth. In the first stage the fibrin of the exudate digests itself in the presence of weak alkali, but in the second stage it has completely lost this power and digests itself only in the presence of weak acid. It is possible that carbon dioxide in the body, acting as an acid, promotes resolution of the exudate by the enzyme. By aspiration of fluid and by other means the characters of the exudate might be modified.

ON CERTAIN ACOUSTIC LIMITATIONS OF THE STETHOSCOPE AND THEIR CLINICAL IMPORTANCE.

DR. LEWIS A. CONNOR, New York, narrated eight cases of aortic insufficiency, in which the murmur was distinctly heard with the naked ear, but which could be heard by no one by means of the stethoscope. In some cases of pneumonia and pleurisy, with effusion, where no bronchial breathing could be heard with the stethoscope, a high pitched blowing sound could be heard with the naked ear. This occurred sometimes twenty-four hours before it could be heard with the stethoscope. The common features of these sounds were: (1) high pitch; (2) faintness; and (3) a blowing quality. The various theories for explaining this difference were discussed. The sounds which are best heard by the ear were the ones which were of the most importance, whereas those heard with the stethoscope were for the most part well heard by the ear. It was unfortunate that in most of our medical schools students were taught to auscultate only with the stethoscope.

DR. S. S. COHEN, Philadelphia, said: As a teacher of medicine, I want to say that Dr. Connor has touched upon an important subject. I find that the sole advantage of the stethoscope to me is in localizing a sound which I previously discovered with the unaided ear.

DR. E. G. JANEWAY, New York, found cases which agreed with those of Dr. Connor; certain deep-seated pneumonias gave sounds to the unaided ear that were not obtained with the stethoscope. The same was true of some of the signs of heart disease.

DR. A. JACOBI, New York, remarked that it made a difference what sized area is covered. The ear covered a larger area and would discover things that no stethoscope would show.

DR. F. P. KINNICUTT, New York, said his personal experience in teaching had been quite in accord with the views expressed by Dr. Connor.

DR. CONNOR, closing, did not feel certain that he had found all the limitations of the stethoscope, but thought the matter worthy of very careful study.

SECOND DAY, WEDNESDAY, MAY 8.

SOME POINTS REGARDING TUBERCULOSIS IN INFANCY.

DR. L. EMMETT HOLT, New York, spoke of the frequency of pulmonary tuberculosis in infants, the importance of house infection and methods of obtaining sputum for examination. He reported 36 consecutive cases of tuberculous meningitis in children in which the bacilli were found in the fluid obtained by lumbar puncture. In the meningitis cases bacilli were frequently found in the sputum when pulmonary signs and symptoms were absent. He referred to the use of tuberculin in diagnosis.

DR. PEABODY asked if any serious symptoms followed removal of the cerebrospinal fluid.

DR. KOBER, Washington, asked whether the feces had been studied for the presence of tubercle bacilli.

DR. CABOT, Boston, said that among 100 children of tuberculous parents, studied at the Massachusetts General Hospital, Boston, tuberculosis had been found in 26.

DR. HOLT, in conclusion, said that no symptoms had been produced by removal of 1 to 3 oz. of cerebrospinal fluid. He had made no study of tubercle bacilli in the feces.

A STUDY OF NORMAL LIVING ANATOMY IN THE FIRST TWELVE YEARS OF LIFE.

DR. THOMAS MORGAN ROTCH, Boston, read this paper, in which he said that the value of the Rœntgen ray in the diagnosis of disease conditions had been much lessened by the difficulty in reading the plates. This depended, in part, on unfamiliarity with the normal. He had consequently made a study of normal Rœntgen ray anatomy at different ages of infancy and childhood and exhibited a series of illustrative pictures.

THE LIFE SAVING VALUE OF DIURESIS.

DR. S. J. MELTZER, New York, gave the result of a series of experiments on the subject contained in this title.

THE HEMORRHAGIC DIATHESIS IN BRIGHT'S DISEASE.

DR. DAVID RIESMAN, Philadelphia, reported two cases of uncontrollable bleeding in Bright's disease. The hemorrhagic diathesis occurring in Bright's disease might take the form of spontaneous bleeding from the mucous membranes — nose, mouth, uterus, intestines — or there might be bleeding into the skin, a true purpura. He said the condition was met with in all forms of chronic nephritis, perhaps more often where there was an associated arteriosclerosis. He considered the cause to be toxemia and in some cases altered state of the vessel walls.

A CASE OF SECONDARY CARCINOMA WITH RECURRENCES IN UNUSUAL SITES.

DR. GEORGE L. PEABODY, New York, reported this case. Patient was a woman, forty-three years old. Four years after removal of carcinomatous right breast she developed severe pains in lower extremities, back and shoulders, which did not yield to treatment. No swellings appeared. Urine increased in amount, occasionally showed casts and albumin. Sleeplessness and mild delirium followed. Lumbar puncture gave normal fluid. Just before death there appeared weakness of the muscles of the right eyelid, right side of face, right palate, with partial deafness of right ear. There was pain in lumbosacral region on attempting to sit upright and on pressure. Urine and feces involuntary. Death occurred from edema of lungs. Autopsy showed metastatic carcinoma of thyroid, one suprarenal, kidneys, one lung, wall of an old cyst of cerebellum, pia of pons, and medulla, perineal lymph sheaths of one trunk, nerve of cauda equina and of trunk nerve itself and of pial covering of cord. In the lung several large vessels were filled with new growth, suggesting an explanation for carcinomatous metastases.

DR. SOLIS COHEN, Philadelphia, referred to a case of metastatic carcinoma, in which the most prominent clinical symptom was dyspnea. There were no local signs in the chest; no effusion. Autopsy revealed an involvement of the bulb by carcinoma.

EXPERIMENTAL OBSERVATIONS UPON THE ACTION OF INTESTINAL ANTISEPTICS.

DR. J. DUTTON STEELE, Philadelphia, said there is no satisfactory method for determining the amount and character of bacterial activity in the intestines. Aromatic bodies in the urine form an inaccurate index. Counts of living bacteria in feces are misleading unless obtained from a fistula in the lower ileum, because many bacteria die in the large intestine. The most satisfactory method and the one used by the author was that of estimation by weight of bacteria in the feces (Strasburger). Attempts had been made to determine the effect of diet on the putrefactive and fermentative groups of bacteria, with no satisfactory results. The author's experiments related to the influence of drugs on intestinal bacteria; the drugs employed were bismuth salicylate and Beta naphthol. Charts were shown, giving the results of experiments. In normal individuals bismuth salicylate caused a diminution in amount by weight of bacteria in the

stools in every instance; the decrease was from ½ to ¼ the normal. There was a return to normal on the second or third day after the drug administration. Similar but less marked results were obtained with Beta naphthol, with the exception of one case; in this there was a mild grade of intestinal inflammation and amount of bacteria was increased. This corresponded with the results of others. The increase might be due to a loss of self-protecting power in irritative conditions of the intestine. The author concludes that ability to affect bacteria in the intestinal tract is dependent upon the condition of the tract; that diet and proper evacuations are important; that irritative drugs tend to increase amount of bacteria.

DR. L. A. CONNOR, New York, asked in discussion whether the diminution affected special varieties more than others, and whether it might not be the harmless forms which were killed off.

DR. STEELE replied that such qualitative estimations had not yet been made.

(To be continued.)

Book Reviews.

Physical Chemistry in the Service of Medicine. By DR. WOLFGANG PAULI, Privatdocent in Internal Medicine at the University of Vienna. Authorized translation by DR. MARTIN H. FISCHER, Professor of Pathology at the Oakland College of Medicine. Seven addresses. First edition. New York & London: John Wiley and Sons. 1907.

This small book consists of a series of seven lectures, given by the author, upon physical chemistry as applied to biological chemistry. It is for the most part theoretical and technical, and valuable only to those conducting research along the line of biological chemistry.

Along the Labrador Coast. By CHARLES WENDELL TOWNSEND, M.D., Author of "The Birds of Essex County." With Illustrations from Photographs and a Map. 289 pages. Boston: Dana Estes & Company, Publishers. 1907.

It is so seldom members of the medical profession venture successfully into the fields of literature that "Along the Labrador Coast" merits more than passing notice. The book is a description of the short trip of the author and Dr. Glover M. Allen to the coast of Labrador last summer to study the birds of that region. Notes made at the time form the basis of the work. The story is told in an easy, colloquial style that holds the interest and yet does not teem with wearisome details. To the lover of outdoor life and to the student of ornithology this book cannot fail to be of interest. The general reader is given a vivid picture of life in Labrador; with the aid of the well-written descriptions of scenery and the very satisfactory illustrations he catches the enthusiasm of the author and feels the call of the wild.

What mistakes there may be are due to errors of observation. One knows the author has seen and done the things he describes, and is not, like some of the nature writers, romancing from the vantage ground of a comfortable city home.

The book is most attractively gotten up: bound in gray linen with a picture on the front cover of a sunset in gold over black mountains. In the foreground is an eskimo in his kyack, also in black, and a white iceberg. The yellow-tinted paper adds to the effectiveness of the numerous illustrations, reproductions from photographs by the author and Drs. W. P. Bolles and E. A. Crockett, other medical visitors to these northern coasts.

A useful feature is the complete index compiled by the author. It contains, besides the chief topics, the common names of the birds and their scientific names as well.

There is need of popular books of just this kind, written by scientific men, and we hope to see further volumes from the same pen.

Saunders' Pocket Medical Formulary, with an Appendix. By WILLIAM M. POWELL, M.D. Eighth edition, thoroughly revised, enlarged and adapted to the eighth revision (1905), of the U. S. Pharmacopœia. Philadelphia and London: W. B. Saunders Company. 1906.

This useful little formulary has reached its eighth revision and been brought into accord with the last edition of the United States Pharmacopœia. We have on previous occasions spoken with favor of this formulary and see no reason whatever to change our estimate. It contains much information compressed into small and convenient form.

A Guide to Diseases of the Nose and Throat and Their Treatment. By CHARLES A. PARKER, F.R.C.S. Edin., Surgeon to the Throat Hospital, Golden Square, London, W. With 255 illustrations. New York: Longmans, Green & Co. London: Edward Arnold.

This is a textbook of 600 pages, in many respects similar to several which have appeared in the last few years. It is founded upon a systematic course of lectures to students and aims at a practical rather than an academic discussion of the various subjects. The operations which have become popular within the last few years, such as the submucous resection, Killian's frontal sinus operation, upper bronchoscopy and enucleation of the tonsils are included, but not recommended with the enthusiasm which the younger members of the profession might expect. The treatment of the numerous conditions which cannot be surgically attacked may be said to be profuse, strenuous and hopeful. It is better that a textbook should teach a student how to abort an inflammation or suppuration than that it should encourage therapeutic nihilism. The etiology of different diseases is well given, better than in most of our similar works. As the etiology of many of these diseases is much in dispute it is unavoidable that no advanced reader will always agree with the author's point of view. The same is true of different methods of operating, but as a whole the book will be found judicial, safe and well written.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 4, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

RUSSELL SAGE INSTITUTE OF PATHOLOGY.

MRS. RUSSELL SAGE has given the sum of $300,000 to found what will be known as the Russell Sage Institute of Pathology, as an adjunct to the City Hospital and the City Home (almshouse), on Blackwell's Island, New York. Mrs. Sage's wishes in regard to the matter were made known in a letter from Robert W. De Forest, her counsel, in which he said: "This institute is to be organized according to the plans and under the direction of Drs. E. G. and T. C. Janeway, with whom are to be associated, as ex-officio members, the Commissioner of Public Charities of the City of New York and the President of the Medical Board of the City Hospital and, as individual members, Dr. D. Bryson Delavan, Dr. Simon Flexner (of the Rockefeller Institute), and Prof. Graham Lusk. The effective work of the institute will depend upon the maintenance and continuance of the helpful relations between the Department of Public Charities and those who are now performing the duties of pathologists to these hospitals. The income of the institute from this source will be based upon the continuance of such co-operation to the satisfaction of the gentlemen named as trustees. Mrs. Sage hopes that as the result of this endowment the research and educational work of these hospitals will be largely increased, to the good of the general public and particularly in dealing with the diseases to which old age is liable."

At a meeting of the Medical Board of the City Hospital, held on June 24, resolutions were adopted, in which the Board thanked Mrs. Sage for her munificent gift and expressed its appreciation of the honor conferred upon the hospital, "realizing that this has been the first occasion upon which a municipal hospital in this city has been so generously provided for by a private individual, for the purpose of fostering medical education and research. It is the hope of the Medical Board," the resolutions go on to say, "that this gift of Mrs. Sage may establish a precedent for others, which may lead to like endowments in other municipal institutions."

The plan for the proposed institution was submitted to Mrs. Sage for her consideration, through Mr. De Forest, in April last, by Dr. Theodore C. Janeway, son of Dr. Edward G. Janeway, who is a visiting physician to the City Hospital. In the communication, which met with so generous a response, Dr. Janeway quoted a recent address of Dr. Welch, of Johns Hopkins University, in which he directed attention to the fact that medical science in the last fifty years had been able to increase the expectation of life for every individual by twelve years, but that this expectation held good only before the age of forty; after which our expectation of life was no greater than that of our forefathers. This, he said, was because the prevention of disease thus far had been through the study and knowledge of infectious diseases which are especially fatal to the young. The preventive medicine of the future must study the causes of the organic changes of later life and, learning these, discover upon what depended the accomplishment of their prevention.

Dr. Janeway explained the purpose of the institute, which it was hoped would be established, as twofold: First, research into the problems of disease and more especially the diseases of advanced life; and, second, the improvement of the city's poorest sick and aged in two of its largest institutions. "These two purposes," he went on to say, "are not distinct, but are closely related, and of the two, I believe the second to be the more important, though to be attained only through the accomplishment of the first. New buildings in prospect, especially a building for the housing of the medical staff, will so much further improve conditions as to make the service of the City Hospital a much more attractive one to young physicians. Four years ago the City Hospital had a pathological laboratory, but no pathologist; some one from the city or some member of the attending staff making the autopsies, and the vast material of the institution being wholly lost to science. The facilities for the application of careful laboratory methods for the diagnosis of the patient's ailments were also very poor.

"At that time the present pathologist, Dr. Oertel, was appointed by Mr. Folks, who was then

Commissioner of Public Charities. For four years he has given his time unreservedly to the building up at the City Hospital of a modern pathological department, modeled after the best German institutes. One year ago he was made pathologist also of the City Home and has since then had charge of the pathological work of both institutions. During this time his constant presence, his teaching of the staff and his example of thorough and self-sacrificing scientific work have immensely raised the character of all the work done throughout the institution and have, more than anything else, contributed to improve the care of the patients in all departments of the hospital. He has also trained men in pathology who have left him for other positions. During all this time he has served the city absolutely without salary, and his assistants, as well, have not received a cent for their services. On such a basis further development is impossible, for men cannot work indefinitely for nothing. There are two alternatives, — first, the attempt to have the city put the pathologist and his assistants upon salaries; second, the endowment of an institute by private beneficence."

ENDOWMENT OF RESEARCH IN MUNICIPAL INSTITUTIONS.

In the foregoing statement of the endowment by Mrs. Russell Sage of a pathological laboratory in connection with the almshouse hospitals of New York, attention is directed to several matters which are worthy of more extended comment.

In the first place, this is the first time in this country, so far as our knowledge goes, in which a large sum of money has been given for the purpose of stimulating investigation in institutions under the immediate control of a city government. It is proverbial that it is difficult to obtain funds for institutions other than those which are governed by private or semi-private interests. The reason for this is, of course, obvious, inasmuch as the changing policies of our rapidly changing city governments might well lead to embarrassment and even to a misappropriation of such funds. In the instance before us this has evidently been guarded against and the co-operation of the city government and charity organizations have been secured to the common end of applying this large sum of money to a definite and highly useful purpose.

In the second place, it is apparent to those who have had any experience in great city institutions that in these hospitals is contained a vast amount of material for study which has in the past too often been neglected and ignored. The possibility which this bequest offers of studying particularly the diseases of advancing life is one which is sure to bring results ultimately of the greatest possible value to the progress of medical science and to the alleviation of suffering. As one walks through the wards of a hospital for chronic diseases, one is impressed with the vast number of conditions which our present knowledge permits us merely to alleviate; one is also struck with the possibilities which these same conditions present, grouped in great numbers, of getting somewhat nearer to the sources and the causes of the distressing and destructive diseases of the latter period of life. The enthusiasm of the past two decades has been largely expended in the study of bacterial diseases with results which every one recognizes and appreciates. There has been no limit set to the possibilities of research along this line, but evidence is accumulating that the attention of many investigators is about to be directed to the still more subtle problems underlying body metabolism and the significance of chronic disease. It is not for a moment to be expected that results in this great field will come quickly, but for this very reason it is time that the medical world should bestir itself toward framing the problems to be solved and toward tabulating the enormous material awaiting study.

It is, therefore, with peculiar gratification that we make note of this unique bequest of Mrs. Sage. The example which it has set should be followed in every large city where its hospitals for chronic disease are crowded with patients, well cared for, no doubt, but on the whole regarded as a hopeless class for whom death can be looked upon only with satisfaction. One of the great steps in progress in the immediate future is, inquestionably, destined to be the utilization of these repositories of chronic disease for the solution of many of the most fundamental problems of medicine. Every effort made toward the improvement of our almshouse hospitals is a step in this direction. New York is evidently destined to lead in this movement, but it will not prove difficult for other cities to follow its example in greater or less degree in developing from every standpoint their municipal hospitals devoted to the care of persons suffering from chronic disease. As we have frequently had occasion to say, Boston has for upwards of ten years been developing its almshouse hospital on Long Island, with gratifying results. The value of the hospital has long since been amply demonstrated.

BOSTON FLOATING HOSPITAL.

THE Boston Floating Hospital has this week begun its season's work under much more favorable conditions than in previous years. Unquestionably this hospital, like those of similar sort in other cities, has completely proved its usefulness as a means of alleviating the diseases of infancy during the summer months. As we have before had occasion to note, a new boat which was in use a part of last year is to be used this summer with improved equipment. For example, this year a refrigerating plant has been put in and the boat will also be propelled by its own engine. The staff of the hospital has been somewhat altered over last year and insures an admirable service.

MEDICAL NOTES.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 3, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 32, scarlatina 33, typhoid fever 9, measles 65, tuberculosis 51, smallpox 0.

The death-rate of the reported deaths for the week ending July 3, 1907, was 16.94.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, June 29, 1907, was 214, against 173 the corresponding week of last year, showing an increase of 41 deaths and making the death-rate for the week 18.53. Of this number 119 were males and 95 were females; 208 were white and 6 colored; 128 were born in the United States, 78 in foreign countries and 8 unknown; 40 were of American parentage, 150 of foreign parentage and 24 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 34 cases and 2 deaths; scarlatina, 28 cases and 2 deaths; typhoid fever, 11 cases and 1 death; measles, 79 cases and 6 deaths; tuberculosis, 43 cases and 25 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 18, whooping cough 2, heart disease 24, bronchitis 5 and marasmus 1. There were 18 deaths from violent causes. The number of children who died under one year was 43; the number under five years, 66. The number of persons who died over sixty years of age was 37. The deaths in public institutions were 79.

There were 3 cases and 4 deaths reported from cerebrospinal meningitis during the week.

DR. HENRY P. WALCOTT HONORED. — Dr. Henry Pickering Walcott, Chairman of the Massachusetts State Board of Health, and Member of the Corporation of Harvard University, received the honorary degree of Doctor of Laws from Yale University at its recent commencement.

APPOINTMENT OF CAMBRIDGE MILK INSPECTOR. — Dr. Ernest H. Sparrow has been appointed by Mayor Wardwell milk inspector of Cambridge, Mass. Dr. Sparrow succeeds Dr. Norris in this office. He is a recent graduate of the Harvard Medical School and has served as house officer at the Cambridge Hospital.

DR. H. W. MITCHELL, SUPERINTENDENT OF THE EASTERN MAINE INSANE HOSPITAL. — Dr. H. W. Mitchell has been appointed superintendent of the Eastern Maine Insane Hospital at Bangor. Dr. Mitchell has for some years been first assistant physician at the Danvers (Mass.) Insane Hospital and has there shown himself a man of exceptional ability and executive capacity.

NEW YORK.

A CENTENARIAN. — It is reported that Mrs. Rosa Harrison died in Trenton, N. J., last week at the age of one hundred and four years. She was a Russian by birth and claimed to have had a distinct recollection of Napoleon's invasion of that country.

OPENING OF SANITARIUM FOR HEBREW CHILDREN. — The Sanitarium for Hebrew Children at Rockaway Park, on the Long Island coast, was opened for the season on June 19. Some two hundred infants and young children were taken on a sail to the institution, and a few of the more serious cases were put in the hospital wards for treatment.

ANTI-SMOKE LEAGUE. — The Anti-Smoke League, of which Charles T. Barney is president, which has been carrying on an active campaign against the large manufacturing and other concerns which pollute the atmosphere of the city, recently established a plant of its own for experimental purposes. The results attained there have been pronounced most satisfactory both by Dr. Walter Bensel, Sanitary Superintendent of the Health Department for Manhattan, and, from the economic side, by J. P. Sparrow, Chief Engineer of the New York Edison Company. By using the new smoke-consuming apparatus and cinder appliances it is found that coal burns with 15% greater efficiency than by the ordinary method of burning it, which creates a nuisance.

A Black List. — At a meeting of the Medical Society of Mercer County, N. J., in which the city of Trenton is located, held on June 22, a resolution was adopted, establishing a "black list," to be kept by the secretary, to which every member of the society is pledged to contribute the names of all persons who avoid paying for professional services.

Honorary Master of Arts for Dr. E. B. Cragin. — Among those who received the honorary degree of Master of Arts at the recent commencement of Yale University was Dr. Edwin Bradford Cragin, Professor of Obstetrics in the College of Physicians and Surgeons, New York.

Health of School Children. — Dr. W. H. Maxwell, superintendent of the public schools, has sent out a circular to all the school principals under his jurisdiction, requesting them to report early in July on a series of questions relating to various phases of the health of the children in their schools. They are asked especially to report on cases of physical defects, and among others specified are malnutrition, chorea, hypertrophied tonsils and defective vision, hearing, speech and mentality. They are also asked to state how valuable they consider the work of the school nurses.

Quiet Zones. — The Board of Aldermen has passed an ordinance establishing "quiet zones" for hospitals in the city, to be indicated by signs at the street corners in the vicinity of these institutions. Under its provisions teamsters and motormen must conduct their vehicles through street blocks within these zones slowly and quietly and motormen may not ring their gongs except in case of danger. Children must not play in the streets, peddlers are forbidden to hawk their wares and no noise which might disturb patients must be made. The Health Commissioner first advised the placing of signs in the vicinity of the hospitals, and the ordinance was introduced and carried to a successful issue through the efforts of the newly organized Society for the Suppression of Unnecessary Noise. The superintendents of fourteen hospitals signed a petition for the passage of the measure and it also received the cordial support of the police department.

Deaths in Three Months. — The quarterly condensed report of the Bureau of Records of the Health Department shows that the number of deaths in the city during the quarter ending March 31, 1907, was 21,182, representing an annual death-rate of 20.06 per thousand of the population, as against an average of 19,539 deaths for the corresponding quarters of the preceding five years and a death-rate of 20.30 per thousand. There was thus a decrease of .24 of a point in the death-rate. If the number of deaths from the principal causes and at certain age-groups are compared with those of the preceding quinquennial averages, corrected to correspond with the increase in population, the following decreases and increases are found: Decreases, — malarial fevers, 11; smallpox, 29; measles, 194; scarlet fever, 93; diphtheria, 113; tuberculous diseases other than pulmonary, 52; meningitis, 117 (of which 76 were epidemic cerebrospinal meningitis); apoplexy, 90; acute bronchitis, 266; bronchopneumonia, 292; Bright's disease and acute nephritis, 165; old age, 74; suicides, 39; deaths under five years of age, 697; deaths at all ages, 259. Increases, — typhoid fever, 9; whooping-cough, 12; influenza, 143; pulmonary tuberculosis, 102; cancer, 88; organic diseases of the heart, 389; chronic bronchitis, 18; lobar pneumonia, 315; diarrheal diseases under five years of age, 109; accidents, 139; homicides, 32; deaths between 5 and 65 years of age, 145; deaths at 65 years and over, 298. The increase in the deaths from pulmonary tuberculosis, notwithstanding the progressively increased activity in the warfare against that disease, is not very re-asssuring; but, on the other hand, it is gratifying to note the diminished mortality from Bright's disease and among children under five years of age.

Instruction to Mothers in Care of Infants. — John D. Rockefeller has provided the funds for the establishment and maintenance of a corps of twenty trained nurses, whose duty it shall be to give instructions to mothers in the proper care of their infants. The proposed system is to be carried out under the auspices of the New York Association for Improving the Condition of the Poor and with the co-operation of the city Health Department and Board of Education. The corps of nurses is to be divided into two sections of ten each. One of these will organize classes for practical instruction to mothers in the district between Thirty-ninth Street and Eighty-ninth Street and Fifth Avenue and the East River, in which the Rockefeller Institute is situated. This territory comprises fifty blocks in all, and one nurse will be assigned to work in each five blocks. The ten nurses of the other section are to be stationed at the recreation piers and at the "Junior Sea Breeze," a plot of nearly six acres on the East River, belonging to the Rockefeller Institute,

where the Association for Improving the Condition of the Poor maintains a playground and hospital camp for sick babies during the summer. The work of all the nurses will be under the direction of Mrs. Helen Ingram, superintendent of the relief work of the Association. The Health Department has agreed to assign a physician to each of the city's recreation piers during the summer months, to act in conjunction with the nurses in educating mothers how to treat their babies when they show signs of illness. The Board of Education is to provide a kindergarten teacher for each pier, whose duty it will be to take care of and amuse the older children, thus allowing the mothers to give more attention to their infants. The daily work of the ten nurses assigned to the territory of fifty blocks will be to visit the families in the district, see every mother of every child under two years of age and give such advice and instruction as may be required. Where a sick baby is found without medical attendance, a physician will be furnished promptly and the nurse will make as many calls as necessary to help the mother in the care of the child. This house-to-house visitation will thus be supplementary to that of the summer corps of physicians of the Health Department in the limited section of the city mentioned. The ten other nurses will visit the tenement houses in the vicinity of the recreation piers and explain to mothers the benefits of fresh air and urge them to go with their children to the piers as much as possible. In connection with the Caroline Rest, a convalescent home for mothers and new-born infants at Hartsdale, Westchester County, the Association for Improving the Condition of the Poor now has a staff of visiting nurses for maternity cases in the tenement houses, in which the women have no monthly nurses of their own.

1. In his President's address before the American Medical Association, June 4, 1907, Bryant discussed the aims and interests of the Association, enumerating them as stated in its constitution, and giving particular attention to such as are of special importance at the present time. The uniting of the profession into one compact organization is progressing rapidly and its advantages if wisely directed are noted. The opportunity and duty of every physician to contribute his share to the healthy growth and wise diffusion of medical knowledge, and especially the opportunities of the country practitioner in observing the different effects of environment on urban and rural patients are mentioned. The subject of medical education and its present deficiencies and needs and more particularly the inadequacy of its endowment as compared with education for the other learned professions is remarked, and it is hoped that substantial improvement can be secured through the convincing influences that can be brought to bear on the public mind. "The promoting of friendly intercourse among American physicians" is regarded by Bryant as the most important announcement in the opening declaration of the aims of the Association, and one that tends most to counteract any possible evil from selfish interpretations of the "material interests of the profession." He knows of no agent so well calculated to contribute to the fostering of the growth and the diffusing of medical knowledge as *The Journal of the American Medical Association*, hence the importance that the tone and wisdom of its utterance be always in accord with the sense of justice of the majority of the profession. How the wellbeing and unity of the medical profession is associated with the welfare of the community in general in the war against disease is noticed and the establishment of a national department of health is favored by Dr. Bryant. The question of reciprocity in medical practice requirements is touched on, and the suggestion made that the examinations should duly consider the experience of the applicant rather than insist too exclusively on modern requirements. As regards medical education, the suggestion, at least, is offered that it may be possible to attempt to realize too strenuous ideals, and that it may be better for the great majority of our medical institutions to "broaden the basis of instruction in established professional knowledge and usefulness rather than risk indulgence in any form of whimsical expediency or of questionable propriety in educational requirements." The pure drug question in the light of recent developments is discussed, as well as the proprietary and patent medicine revelations, and the work of the Council on Pharmacy and Chemistry of the American Medical Association is highly commended. It is also suggested that a careful scientific consideration of the mineral springs of the country would be similarly useful. In closing, the civic duties of the medical profession are alluded to, and warning given against the dangers of a growth of a spirit of paternalism, which is a frequent by-product of organized power.

5. Ballenger's article aims to combat the general lack of definite knowledge of the diseases of the prostate. These diseases he enumerates and classifies. Most attention is devoted to chronic prostatitis, in which the largest number of diagnostic errors are made. The reason for this is that most physicians rely upon palpation alone and do not realize that chronic inflammation may exist without enlargement or other palpable abnormality. In such cases the diagnosis may be made by examination of prostatic secretion as obtained by massage, pure or diluted with urine. In this secretion two elements if present are diagnostic; pus and proteid substances, albumin, globulin or albumose, detected by the appearance of a white ring on addition of saturated $MgSO_4$ (9 parts) and HNO_3 (1 part). Pus or proteid in fluid passed after prostatic massage, but absent from that passed before massage renders the diagnosis of prostatitis positive.

6. In a preliminary communication, Beer publishes the histories of two cases which seem to point to a new diagnostic sign of the involvement in suppuration of the kidney parenchyma. In the first case the patient discharged methylene blue stained pus in the urine at intervals up to two and three-fourths years after the last administration of the drug. The second patient had pyelonephritis (verified by nephrotomy) and had recurrent discharges of methylene blue stained pus over a month after the last administration of the drug. He produced a pyelonephritis in a dog and then for several days administered methylene blue. The kidney was removed two weeks later and, after treatment with oxidizing agents, showed multiple bluish gray pus foci throughout its substance. He summarizes

his conclusions derived from the facts so far as follows: (1) There is no differential diagnostic sign between simple pyelitis and pyelonephritis. (2) Pyuria from the upper urinary tract may be due to either of these conditions. (3) By use of the above described methylene blue test it would seem that a differential diagnosis may be made. (4) Methylene blue is deposited in the parenchymatous abscesses and may be stored in these for years. (5) A late discharge of methylene blue, bound to the pus, is indicative of the rupture of such parenchymatous abscesses into the pelvis of the kidney and is consequently diagnostic of pyelonephritis.

7. Simon reports a case of meningococcus septicemia in which meningococci were demonstrated in smears of blood obtained from the ear. Eight cases are on record where meningococci have been obtained by blood-culture. [F. W. P.]

5. CROTHERS, T. D. *Some Effects of Spirit and Drug Taking on the Upper Air Passages.*

4. Einhorn describes a new modification of the benzidin test for blood in the stomach contents, feces and urine. It consists of testing with paper sensitized by the use of benzidin. The paper is immersed in the solution to be examined and a few drops of peroxide of hydrogen are added, when a blue color is formed if blood is present. The blue or green color appears in a few seconds and we should not wait more than a minute for the reaction to appear, as after that the color may appear from the presence of other substances than blood. HCl may cause the reaction after two or three minutes. The benzidin test can be recommended as a preliminary test: a strong reaction or no reaction at all gives a reliable test. [F. W. P.]

NEW YORK MEDICAL JOURNAL.

7. ALGER, E. M. *A Case of Eyestrain Mistaken for Appendicitis and Cholelithiasis.*
8. BEERS, N. T. *Impetigo Contagiosa.*

1. Taylor discusses at length a large number of types of deformity of the penis, including the indurating edema of syphilis, most commonly accompanying the hard chancre, deformities from tertiary syphilitic lesions and changes of the type of elephantiasis. The etiology of this last condition is probably complex; gonorrheal urethritis probably plays a part and secondary infections may be a factor. Some cases follow trauma or operations for the removal of inguinal glands. The clinical appearances and the microscopic pathology of the abnormalities described are shown by illustrations.

2. Keppler calls attention to the lack of care too commonly shown in the treatment of weak foot. Of this disorder three common types are described: the painful weak foot without deformity, the deforming weak foot without spasm and the spastic deforming weak foot. The treatment must be long continued, six to ten months being the average time demanded. The first essential in prophylaxis as well as in treatment is to obtain proper shoes. Next, to correct the disorder already present, the general tone of the foot structure is to be improved by active exercises, which are described, by manual manipulation, and by the use of mechanical apparatus, especially valuable in advanced types combined with spasm. During this treatment what gain is made is to be retained by supports, best by the Whitman plate fitted to plaster casts and corrected at stated intervals as improvement occurs. The worst cases may require operation by open incision, but before resorting to this, it is well to try correction by manipulation under an anesthetic, followed by retention in a plaster of Paris dressing for four to six weeks, followed in turn by treatment with exercises and plates as in ordinary cases. [F. W. P.]

1. Gowers gives the term " vaso-vagal attacks " to certain prolonged seizures, the symptoms of which consist chiefly in the disturbance of some of the functions of the pneumogastric, for the most part sensory and subjective. There may be slight mental change and disturbance of the vaso-motor center, causing constriction of the vessels and coldness of the extremities and occasionally some sensory impairment and slight tetanoid spasm. Attacks are usually one-half hour or more in length. The onset is sudden and the ending gradual. These cases are generally confused with forms of hysteria. The characteristic vagal symptoms are chiefly sensations referred to the stomach, heart or respiratory system. There is seldom any real loss of consciousness, but merely a slowing of the mental processes. He gives details of 11 cases. The treatment consists of general measures to strengthen the constitution. [J. B. H.]

5. DOW, A. *A Case of Tuberculous Meningitis in a Boy Treated with Tuberculin; Recovery; Recurrence and Death.*

1. Murray urges a more careful study of the respiration rate in pneumonia in children; he thinks a record of this is of far more importance than that of the pulse or temperature. He differs with other authorities who attempt to classify pneumonias of childhood into distinct groups, and believes that this is not only a waste of time but an actual impossibility, as the different types vary so very greatly. He believes in estimating the individual value of each sign and symptom on prognosis and treatment, rather than placing the case in some hypothetical group by means of these signs and symptoms and then dealing with the prognosis and treatment of that group as a whole. He analyzes 54 consecutive cases under his care.

4. Phillips presents 12 cases of acute or subacute colitis in detail, with a careful consideration of symptoms, complications and sequelae, among which he mentions a marked tendency to embolism in distant organs, usually after the acute stage has subsided. Anemia of a very intense and lasting nature is apt to follow. No specific

organism has as yet been discovered. He considers it a grave and dangerous disease, with the prognosis always in doubt. In treatment he strongly recommends mercury in small doses, combined with opium if it produces purgation. [J. B. H.]

8. *MORELLI, G. *A Case of Primary Cancer of the Lungs.*

2. Hirsch, avoiding pneumothorax by modern operative methods, was able to ligate the descending branch of the left coronary artery in 8 dogs and 2 monkeys, without affecting the heart beat, except some transitory arrythmia at the moment of ligating the artery. These animals lived in apparently normal condition and without any signs or symptoms referable to the heart. After 2, 3 and 4 weeks they were killed and the hearts examined anatomically. In all the experiments with dogs a small myomalaceous infarct was found at some distance from the point of ligature toward the apex. In no case did the infarct correspond to the entire area supplied by the ligated artery. Spalteholz, through a special injection method, which he has used successfully in tracing the circulation of the small arteries in the muscles and skin, was able to prove that the coronary arteries are not terminal arteries in the sense of Cohnheim, but that they anastomose freely with each other, in a network near the heart surface and also with the vasa vasorum, in an arrangement very similar to that he has described as occurring in embryonic smooth muscle tissue. Where the myocardium is thick, branches from the superficial net work descend and anastomose freely under the endocardium. Each papillary muscle contains numerous arteries which anastomose with one another. The coronary arteries in the dog are arranged in a similar manner to those of man. One dog died of hemorrhage from the wound and was found to have a red infarct corresponding to the whole region supplied by the artery, showing that the weakened heart muscle had not the strength necessary to establish the collateral circulation. This would seem to indicate the need of employing quick-acting heart stimulants in cases of angina pectoris with a low blood-pressure in order to limit the area of possible infarct by increasing the collateral circulation. The experiments on monkeys were not so striking anatomically, owing to slight differences in the anastomosing of the arteries. The article is accompanied by some very excellent illustrations.

8. Morelli reports, with pathological examination, a case of primary cancer of the lungs, interesting in that it occurred in a young man of 28 years, without metastases and developed bilaterally. Microscopical examination made it most probable that it originated in the epithelium of the bronchial glands.

7. *WAELSCH, L. *A Case of Atoxyl Poisoning.*
8. ARNDT, G. *A Glove for Electric Massage.*

1. Repeated injections of yeast render animals less susceptible to microbic infections. Deutschmann has found the serum of such animals to possess marked curative properties for various infectious diseases of man. This action is presumably due to protective substances. In pneumonia an evident effect was manifest in one half of 21 cases, the temperature fell rapidly and convalescence set in. The serum is also very useful in infections of the eye, for which it was originally intended. The pneumonia charts which illustrate the article show a striking fall of temperature soon after the injection, but the number of observations is too small to prove the value of the serum.

2. The hyperemia occurring after the application of cold to the skin is due, according to Ritter, not to the cold itself, but to the damage to the tissues. It is a sign of the need of the tissues for more blood and is, therefore, to be encouraged, not combated. That it is not merely the result of dilatation of the arterioles is shown by the fact that local anemia caused by adrenalin is not followed by hyperemia. The attraction of the necrotic tissues for blood is apparently a biological phenomenon and not merely reflex, for hyperemia occurs after freezing, when all the nerves to the part have been cut. Active and passive hyperemia are not opposed to one another, but serve the same purpose, the former, to be sure, more effectively. Thus active hyperemia is the rule after freezing, but venous congestion is seen when there is a lack of arterial blood. Ritter's therapeutic researches have shown that in chronic frost-bite the production of arterial hyperemia by means of hot air is a sovereign remedy, leading to cure in a short time. It should be employed at high temperatures for ½ to 1 hour daily, the patient being carefully watched on account of the danger of fainting. For acute frost-bite, passive congestion by the elastic bandage is to be preferred. It causes rapid relief of the pain and itching, healing of the ulcers and prompt demarcation of gangrenous areas. The bandage should be applied for 6 to 12 hours daily, taking care that the part should show *increased* heat and a bright red color. In anemic persons a previous application of hot air enables one to obtain the proper congestion with the bandage. The judicious use of hyperemia is thus, according to Ritter, the best method of treating both acute and chronic frost-bite.

4. Brentano relates a case of ileus in which a very large gallstone was removed from the ileum by operation; a second equally large stone came down from the gall-bladder ten days later and caused fatal peritonitis by stretching the stitches at the site of the previous enterotomy. A round facet on the proximal part of the first stone indicated that a second remained behind. Brentano recommends that in intestinal obstruction due to gallstones the intestine be palpated for further stones and that, if facets are present, the gall bladder be opened also.

5. Bruns reports 3 cases of anguillula infection in man and gives a thorough description of the parasite. Its place in pathology is still a matter of dispute, its practical importance is slight on account of its rarity, in temperate climates at least.

7. Atoxyl, or met-arsenious acid-anilid, was introduced into the treatment of skin diseases as a non-toxic arsenic compound. Waelsch's case of poisoning after the administration of 2.6 gm. atoxyl in 27 injections, and several other cases from the literature, show that it is not so harmless as has been claimed. The symptoms consisted of a mixture of arsenic and anilin poisoning, consisting of malaise, pains, fever, headache, conjunctivitis, cough and strangury. The patient recovered. [W. T.]

BERLINER KLINISCHE WOCHENSCHRIFT, No. 16.

5. This is an interesting study by Zuelzer on the nature of the glycosuria produced by the injection of adrenal extract. He passed defibrinated normal dog's blood through the livers of dogs, and found that in the case of normal livers the increase of sugar in the blood after the passage was about 12%; that with livers after the injection of adrenal extract was 50% to 113%; that with livers of dogs with extirpated pancreas was 66%. The hypothesis was formed that normally the adrenal secretion is neutralized by pancreatic secretion and that in pancreatic diabetes it is the lack of this neutralization which allows the adrenal secretion to act on the economy in full force and to produce glycosuria. Further experiments lent a certain support to this view, for by simultaneous injection of pancreatic extract he was able in every instance to prevent the adrenal glycosuria. Moreover, Zuelzer succeeded in 2 dogs in preventing the glycosuria following extirpation of the pancreas by ligating the suparenal veins; the dogs lived 36 hours after operation. His results certainly suggest the possibility of some relation between the adrenals and the pancreas in pancreatic diabetes.

6. Fellner and Rudinger report the results of tests of the cardiac function in 70 cases by Katzenstein's method. This consists in the comparison of the blood pressure before and during compression of both femoral arteries. They confirm in the main Katzenstein's statements and recommend the method for use in conjunction with the usual methods of examination. They found that the normal heart responds to compression by a rise in pressure of 5–10 mm; with the sufficient hypertrophic heart the increase is greater, up to 20 mm. A stationary pressure or a fall in pressure is a sure sign of cardiac weakness, which may be assumed also in the case of hypertrophic hearts if the rise is only slight, say 5 mm. In chlorosis, anemia and tuberculosis, diseases in which cardiac weakness has been assumed but not proven, they found a notable decrease in pressure during compression. Contrary to Katzenstein, they were unable to find any constant relation of the pulse rate to compression. [This new method of estimating objectively the function of the heart deserves further trial. It is not adapted to very sick cardiac patients, in whom the sudden increase of peripheral resistance may prove disastrous. W. T.]

7. Benda offers convincing proof that the "silver spirochete" is really a spirochete and not, as Schulze and Saling claim, merely connective tissue, nerve, or elastic fibers. He demonstrates that the central "giant-cell-like" area in the miliary gumma of congenital syphilis consists of a mass of spirochetes, thus offering important anatomical evidence of the etiological rôle of the spirocheta pallida.

Miscellany.

CHRISTIAN SCIENCE AND THE LAW.

Clarence W. Byrne, the Christian Scientist, who was arrested some time ago, at the instigation of Coroner Acritelli, for permitting his daughter, a child of six years, to die of bronchopneumonia, on May 4, without medical attendance, was found guilty, on June 28, 1906, in the Court of Special Sessions, of violating that section of the Penal Code which makes it a misdemeanor for a parent or guardian to fail to provide medical attendance for a minor. The penalty for this offense is imprisonment for a year, a fine of $500, or both of these; but sentence was postponed until July 12, on motion of counsel for the defense, in order to allow briefs for a new trial to be filed. This case is one of special interest, from the fact that on the day when it first came up for trial, July 11, Justice Denel, before whom it was to be tried, decided to dismiss it, on the alleged ground that "the law under which this defendant was arrested had been nullified and superseded by a more recent one, giving Christian Scientist healers the right to practice healing." At the request of the prosecuting attorney, however, the judge consented to postpone the trial until the following day, in order that the points of law involved in this ruling might be investigated. On the next day it was successfully argued by the prosecution that even if the contention thus made were now valid, it did not apply to the case of Byrne, from the fact that his child died nine days before the new legislation on medical practice went into effect. In the bill recently passed by the legislature, which was commonly known as the medical unification bill, but the correct title of which was "An act to regulate the practice of medicine," it is provided that "no person shall practice medicine unless registered and legally authorized to do so"; but a paragraph in the new law, it appears, is devoted to certain exceptions and in this it is stated that "the law shall not be construed to affect the practice of the religious tenets of any church." As to whether this section of the law applies to Eddyite healing, and, if so, how far it affects the force of previously existing statutes, such as the one under which Byrne was convicted, has not yet been settled by any decision in the courts.

Correspondence.

DAVIS MEMORIAL FUND.

Boston, June 26, 1907.

Mr. Editor: At the last annual meeting of the Massachusetts Medical Society the Councilors voted to appropriate three hundred dollars towards the Davis Memorial Fund, provided not less than two hundred dollars was raised by private subscription. A considerable portion of this amount has already been subscribed, and through you permit me to invite additions to this fund in such sums as the members of the Massachusetts Medical Society feel disposed to contribute. All subscriptions sent to me will be duly acknowledged.

The character of the Memorial will be determined by the officers of the American Medical Association.

The committee desire that this memorial to Dr. Davis shall be shared in by the profession in general, since to Dr. Davis we are indebted for the founding of the American Medical Association and its present exponent, the journal of the association, now the leading medical journal of the world. To him also in large degree is due the organization of some of the state societies and the development of medical education to its present high standard in America. Although justly celebrated as a practitioner of medicine, a teacher, a writer of textbooks and the founder of two great medical schools, he is pre-eminent above all others as the great organizer of the medical profession in America. To such a memorial the medical men of this country are gladly furnishing their contributions. Massachusetts honors herself in honoring this great pioneer in the development and the carrying to a high standard the medical profession in the West.

Truly yours,

Henry O. Marcy, M.D.,
Chairman of the Committee.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING JUNE 29, 1907.

E. H. MARSTELLER, surgeon. Unexpired portion of sick leave revoked, and ordered to the Naval Recruiting Station, Baltimore, Md., July 1.

G. M. MAYERS, passed assistant surgeon. Detached from the "Marietta" and ordered to the "Ohio."

I. S. K. REEVES, passed assistant surgeon. Detached from the "Franklin" and ordered to the "Marietta."

J. T. KENNEDY, passed assistant surgeon. Detached from course of instruction at the Naval Medical School, Washington, D. C., and ordered to Danville, Va., for duty with recruiting party No. 3.

R. C. HOLCOMB, passed assistant surgeon. Detached from course of instruction at the Naval Medical School, and ordered to the Naval Hospital, Norfolk, Va.

H. L. BROWN, assistant surgeon. Detached from course of instruction at the Naval Medical School, and ordered to the Naval Recruiting Station, Oklahoma, Okla.

R. G. HEINER, assistant surgeon. Detached from course of instruction at the Naval Medical School, and ordered to duty with Marine Detachment at Camp Harrington, Williamsburg, Va.

F. E. PORTER, assistant surgeon. Detached from the "Rhode Island," and ordered to the "Franklin."

B. F. HAINES, acting assistant surgeon. Ordered to Naval Hospital, Philadelphia, Pa.

D. H. CASTO, acting assistant surgeon. Detached from the Naval Recruiting Station, Baltimore, Md., and ordered to Washington, D. C., July 1, for examination for appointment as an Assistant Surgeon in the Navy, and then to report to the Surgeon-General of the Navy for further orders.

J. T. MILLER, acting assistant surgeon. Detached from course of instruction at the Naval Medical School, and ordered to the "Rhode Island."

M. DONELSON, acting assistant surgeon. Detached from duty with Naval Recruiting Party No. 3, and ordered to Washington, D. C., July 1, for examination for appointment as an Assistant Surgeon in the Navy, and then to report to the Surgeon-General of the Navy for further orders.

G. P. BRADLEY, medical director, retired. Detached from the Navy Yard, Portsmouth, N. H., and ordered home.

E. Z. DERR, medical director. Detached from the Navy Yard, Boston, and ordered to the Navy Yard, Portsmouth, and to additional duty in command of the Naval Hospital at that place.

J. M. EDGAR, surgeon. Detached from the "Wabash," and ordered to the Navy Yard, Boston, Mass.

K. OHNESORG, passed assistant surgeon. Detached from the Navy Yard, Boston, and ordered to the "Wabash."

J. C. BYRNES, medical inspector. Detached from the Naval Academy and ordered to duty as fleet surgeon, first division, Pacific fleet, on board the "West Virginia," sailing from San Francisco, Cal., about July 25.

J. D. MILLIGAN, pharmacist. Detached from the "Fish Hawk," and when discharged from treatment at the Naval Hospital, Norfolk, ordered home, and granted sick leave for six weeks.

APPOINTMENTS.

DR. JOHN T. BOWEN has been appointed Edward Wigglesworth Professor of Dermatology at the Harvard Medical School.

DR. MAURICE H. RICHARDSON has been appointed Moseley Professor of Surgery at the Harvard Medical School.

DR. CHARLES M. GREEN has been appointed Professor of Obstetrics at the Harvard Medical School.

DR. CLARENCE JOHN BLAKE has been appointed Walter Augustus Lecompte Professor of Otology at the Harvard Medical School.

DR. OTTO K. O. FOLIN has been appointed Associate Professor of Biological Chemistry at the Harvard Medical School.

DR. GEORGE B. MAGRATH has been appointed Instructor in Legal Medicine at the Harvard Medical School.

RESIGNATION.

EZRA RIPLEY THAYER, lecturer on the Relation of the Medical Profession to the Law and the Courts, has resigned from this lectureship at the Harvard Medical School.

RECENT DEATHS.

DR. WILLARD PARKER, of New York, son of the late Willard Parker, the eminent surgeon, died on June 24, from cardiac disease, resulting from rheumatic trouble. He was graduated from Columbia College in 1866, and from the College of Physicians and Surgeons in 1870. He did not care for surgery, and the surgical practice of his father was succeeded to by his brother-in-law, Dr. Daniel M. Stimson, who married Miss Edith Parker.

DR. WILLIAM M. NELSON, a physician well known throughout Central and Northern New York, and for over thirty years a practitioner at Taberg, Oneida County, N. Y., died at his home on June 26. He was sixty-seven years of age, and was graduated from Jefferson Medical College, Philadelphia, in 1869.

DR. ISRAEL HART, of Pennington, Mercer County, N. Y., died on June 23, at the age of seventy-nine years. He was graduated from the medical department of the University of Pennsylvania in 1853, and during the Civil War served as Surgeon of the Thirty-eighth Regiment, New Jersey Volunteers. He had previously practiced at Pennington, and returned there at the close of the war. He is succeeded in practice by a son, Dr. Edgar Hart.

BOOKS AND PAMPHLETS RECEIVED.

Practical Gynecology. A Comprehensive Text-book for Students and Physicians. By E. E. Montgomery, M.D., LL.D. Third revised edition. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1907.

La Question de Régime dans les Stations Hydrominérales Françaises. Par le Dr. Mazeran. Paris. 1907.

The American Illustrated Medical Dictionary. By W. A. Newman Dorland, A.M., M.D. Third edition, revised and enlarged. Philadelphia and London: W. B. Saunders & Co. 1905.

Saunders' Pocket Medical Formulary. By William M. Powell, M.D. Eighth edition, thoroughly revised and enlarged. Philadelphia and London: W. B. Saunders Co. 1906.

Prevalent Diseases of the Eye. A Reference Handbook, Especially Adapted to the Needs of the General Practitioner and the Medical Student. By Samuel Theobald, M.D. Illustrated. Philadelphia and London: W. B. Saunders Co. 1906.

Obstetrics for Nurses. By Joseph B. De Lee, A.M., M.D. Second edition, thoroughly revised and enlarged. Illustrated. Philadelphia and London: W. B. Saunders Co. 1906.

THE SEGREGATION OF CONSUMPTIVES.

THE ANNUAL DISCOURSE DELIVERED BEFORE THE MASSACHUSETTS MEDICAL SOCIETY, JUNE 12, 1907.

BY J. F. ALLEYNE ADAMS, M.D., PITTSFIELD, MASS.

Mr. President and Fellows of the Massachusetts Medical Society:

The physician's path, though a good one to follow, is neither smooth nor easy. His life is a warfare, from the diploma to the grave — a warfare demanding the constant use of all his powers, but whose visible rewards are not commensurate with his expenditure of force. He strives not for himself, but for others, and others enjoy the fruits of his victories. But this fact does not deter men from entering our profession. Rather does it tend to draw into it those who wish to lead fruitful lives, and it gives to the medical vocation a satisfaction which is beyond all material returns. The physician is not a soldier of fortune, seeking only gold and glory, but a crusader enlisted in the army of God, and fighting for the rescue of suffering humanity. This is the crowning glory of the doctor's life, and it is this unselfishness which ennobles his profession, and gives him a great and peculiar influence — an influence which is generally recognized by the community and which brings him great opportunities for usefulness.

Thus it comes about that a medical practitioner is, to a greater or less extent, a missionary. He is always finding and doing some work, unpaid or underpaid, for his fellowmen, because his training and his position render such work possible and natural. In freely serving the poor, in their homes or in hospitals, his opportunities for good are not exhausted. In all philanthropic measures he is to be relied upon as a helper, and in those directly pertaining to the public health, he is naturally a leader. He has unequaled facilities for disseminating knowledge, for awakening interest and for guiding benevolence. The evidences of this influence are to be seen on every hand. Have you not all exerted it? and have not your laborious lives been brightened and sweetened by your success?

If the influence of the physician in his individual capacity is so great, how much greater must be that of the profession as a whole! When this acts as a unit great things can be accomplished, and our medical societies render such action possible. This organized force has done good work in the past: it has persistently opposed error with truth, ignorance with knowledge, charlatanry with science; it has given to the world the benefit of those marvelous discoveries of the past century which have prevented untold suffering and rescued millions from death; and it stands ever ready to champion every good cause whose object is to save human lives and make them better worth living.

It is therefore the thing to be expected that we, Fellows of The Massachusetts Medical Society, on this our anniversary, should ask ourselves and each other, "What is the cause which this year most urgently demands our help?" I think you will agree with me that the one paramount problem which to-day confronts us is the suppression of tuberculosis, and that this is the cause which now calls most loudly for our united and hearty support.

The knowledge that it is possible to exterminate this scourge of our race has deeply stirred the minds of men — and flooded the world with the light of a new hope. A mighty war is now in progress — a war which is uniting under a common banner people of every race, color, language, nationality, class, party and creed. Already have notable victories been won, but we are still in the early stages of the campaign, and it will require years of valiant and united onslaught to rob tuberculosis of its terrors. Meantime, the people look to us for leadership; and it is incumbent upon us to consider, year by year, what battalions are to be organized, what engines of war constructed and what tribute levied upon the community for the successful conduct of the campaign.

As a contribution to the discussion of this subject, I will ask you to consider with me that one of its branches which seems to me of the highest importance, namely, the prevention of consumption by the separation of the sick from the well.

Since pulmonary tuberculosis is known to be actively infectious, through a specific germ, it is perfectly evident that the isolation of all infected persons would, in a few years, stamp it out. It is the leprosy of our time; and, as leprosy is kept under control by the segregation of lepers, so may consumption be eradicated by the segregation of consumptives.

Let us suppose all the power in our country to be centered in a despot of unlimited power and wealth, and also filled with a burning desire to confer great blessings upon his subjects. Such an one might say, "Consumption is the greatest enemy of my people. I will destroy it, and that quickly." Could he do it? He could; and how? He would order the formation of many great camps, or enclosures, where all consumptives would be forcibly colonized. These would be placed not far from the cities and towns, but far enough to find pure air and sunshine. There would be tents, cabins or shacks for the incipient cases, and hospitals for the advanced. There would be ample space and much freedom within the camp, but no passing the bounds. Here many early cases and some of the advanced ones would be restored to health and be permitted to return to their homes, while those who must die would have their illness brightened by good care and every possible alleviation. By this removal of consumptives, infection would cease, and since the patients would no longer leave the disease as a legacy to their families, new cases would grow fewer and fewer. The change in ten years would be marvelous, and if our supposed despot should live to the good old age he would deserve, he would see his camps nearly deserted and consumption dwindling to an insignificant place in the mortality tables. At the end of his benefi-

cent reign, his grateful people would erect a monument inscribed with these glorious words, "To the Conqueror of Consumption."

The day of despots has now gone by, but the power which they wielded still remains, vested in the people, and the people are able to accomplish this same result. When once they are educated up to the idea, when they fully understand that the thing can be done and that the doing of it will save multitudes of lives and remove one of the chief causes of suffering, poverty and sorrow, will there not be a great popular uprising, when the people themselves will demand the enforcement of this act of depotism, which will separate the infected from the uninfected, to the end that the plague may be stayed? They will be a little longer about it than our despot would have been, — measures too arbitrary and violent might engender sedition and wreck the treasury, — and they will try to bring about the desired result without too much restraint of personal liberty and without danger of financial disaster, but in good time this thing will be done. It is safe to prophesy that the days of tuberculosis are numbered and that future generations looking back upon our time will say, "There were giants in those days, for they destroyed that arch-enemy, consumption."

Through the untiring efforts of a great number of medical men, and some very earnest laymen, the people are being taught the value of local associations, of medical inspection, of visiting nurses, of anti-spitting regulations, of disinfection of houses, of registration of cases, of out-door life, of dispensaries and of sanatoria for incipient cases. But the most urgent need of all, the hospital for advanced cases, is not yet sufficiently recognized. It is not a philanthropic interest in the patients themselves which is the chief reason for building these hospitals, though this would be reason enough; but there is a far more weighty one,— the prevention of infection, whereby alone the endemic may be arrested. The public need be shown the necessity for such hospitals, and state, city and town governments should be brought to realize that the appropriation of public funds for this purpose is a patriotic duty on grounds not only of humanity, but of self-preservation. The vast expense, however, will be an almost insuperable obstacle to the sufficient carrying out of the plan. But it is a war measure and we must learn to consider it as such. "Millions for defense" are not begrudged against human enemies, and why should they be against the far more hostile and bloodthirsty bacilli? But, for the relief of the overburdened tax-payers, we need also to enlist the interest of private philanthropy. Persons of wealth should be shown that in no way can they use their means to help their brother-men more wisely and efficiently than by building and maintaining these hospitals for consumptives. This needs to become the great popular charity.

The state of Massachusetts, which built at Rutland the first state sanatorium for incipient cases, is wisely undertaking to provide also for advanced cases. A "Commission to investigate measures for the relief of consumptives" was appointed a year ago, and presented its report last March. So admirably was this report prepared, so wise were its suggestions and so convincing were its arguments, that already has the legislature passed bills carrying into effect nearly all of its recommendations. These bills provide, first, for the immediate construction of three infirmaries for tubercular patients, of 150 beds each; second, for the appointment of state inspectors of health; third, for compulsory registration of cases; and fourth, for giving greater effect to the anti-spitting law. Surely this is a remarkable result. A commission which has brought the enactment, in a single session, of so many beneficent laws is entitled to our gratitude and admiration. Three of its six members are Fellows of The Massachusetts Medical Society, and it is fitting that their names should be mentioned and remembered. They are Dr. H. P. Walcott, Chairman of the Commission and Chairman of the State Board of Health, Dr. A. S. MacKnight of Fall River, and Dr. C. S. Millett of Brockton, Secretary of the Commission. Their lay associates are Messrs. Brackett, Adams and Porter.

To this roll of honor should be added the name of Senator Frank M. Chace, of Fall River, who had charge of the "Three Sanatoria" bill; of Ex-Representative Googins, of Cambridge, who for four years, from 1901 to 1904, tried to secure the passage of a similar bill, and of Senator Frank G. Wheatley, M.D., another Fellow of our Society, who had charge of the bill providing for State Inspectors of Health.

There are many others who have been active in securing this beneficent legislation, but I will here add but one other name, that of Governor Curtis Guild, Jr., who, in his last inaugural, recommended measures for the relief of consumptives, and who has done all in his power to advance it.

This commission undertook a census of consumptives in Massachusetts and obtained from physicans reports of 7,779 cases, of which about one third are classed as incipient. But, as the Secretary of the Commission stated to a committee of the legislature, the actual number of cases is probably double these figures, which seems extremely likely, when we consider that there are 5,000 deaths annually. It is quite safe to place the number of consumptives in the state at 15,000, of whom 5,000 or less are incipient, and 10,000 or more advanced. Let us inquire how nearly the three new infirmaries will come to accommodating this number.

We have already in the various institutions of the state about 400 beds for incipient cases and 500 for advanced — making 900 in all. The 450 beds in the three new infirmaries will make 1,350. Each bed will be sufficient for two or perhaps three patients a year. If we say three patients a year, the 1,350 beds will provide for 4,000, leaving 11,000, or nearly three quarters, unprovided for.

The building of these infirmaries, therefore, is not going to be enough to stamp out the disease,

but it is a long step in the right direction; it will afford much relief and will be an object lesson to demonstrate their value and the necessity for increasing their number in the future.

It will not take long to show the value of this separation of advanced cases. When we remove them from their homes and from public places, the number of incipient cases will begin to fall off. Every person with advanced tuberculosis is likely to infect at least one other person, so that under present conditions there is no possibility of the disease dying out.

The long continuance of the disease renders impossible such house quarantine as is enforced in the case of smallpox, scarlet fever, measles and diphtheria. However careful may be the patient and his family, there is always danger that, through some relaxation of the rules, germs may be conveyed to another person. Such accidents may happen through forgetfulness, weariness, excitement, intemperance or delirium. In the last stages of the disease the patient often expectorates at random all over the bed, the floor and even the walls, thus endangering the wife or daughter who is in attendance, other members of the family who pass through the room, and children who may be creeping upon the floor. Such cases ought not to die at home. They should be moved to a hospital, where they can have more comforts, and not be sowing the seeds of disease among those whom they love best. This separation will be resisted at first on sentimental grounds, but the arguments for it are so strong that resistance will lessen with time. Especially will this be the case if these hospitals are not placed at such a distance as to forbid frequent visits from members of the family. These visits, which can be made without danger, will relieve homesickness and make the separation less complete and depressing than it would be if the patient had to be removed far from home.

The sanatoria for incipient cases are doing a great work restoring to health a considerable number of persons who would otherwise die. At Rutland, during the eight years since the sanatorium was opened, the number of cases discharged "arrested or apparently cured" has been 1,487, or over 41% of all cases treated. This is a handsome showing; it justifies the outlay for the sanatorium, and is full of encouragement for the future; but, compared with the number of consumptives in the state, the figures are not large. It has been the policy of the sanatorium to restrict it to incipient cases, and such are never refused, but hitherto there have not been enough such applicants to fill the beds, and rather than to let the beds remain empty, a sufficient number of moderately advanced cases to fill them have been received. At present the number of incipient applications has increased to such an extent that few advanced cases can be received, and the question every day arises, What can these people do? The doors of Rutland are closed against them, and properly so, for these incipient cases have the prior claim; but their need is great, and there is, as yet, no place for them to go.

The number of rejected applicants last year was about a thousand, and if we add to these nearly 400 more who, after a few weeks or months, were found not to respond to the treatment and were discharged, these alone are sufficient to fill the three new hospitals which are now proposed. This proves the urgent necessity for their speedy construction.

In Massachusetts the provision for incipient cases at present consists of the State Sanatorium at Rutland, with 350 beds; and two private sanatoria — that of Dr. Bowditch at Sharon, and that of Dr. Millet at East Bridgewater, each with about 20 beds.

For advanced cases, about 250 beds, or half of all those in the state, are in Boston institutions, namely, the Channing Home, House of the Good Samaritan, the Cullis Consumptives' Home, the Free Home for Consumptives, St. Monica's Home for Colored Women and Children, the Boston Almshouse and Hospital, Carney Hospital.

Outside of Boston, the principal provision is at the Tewksbury State Hospital, which has 140 beds for consumptives, besides a camp of 36 beds. The other institutions, where advanced cases are received, are: the Holy Ghost Hospital for Incurables, Cambridge; Lowell City Hospital, Fall River City Hospital, several private hospitals in Rutland and Miss Sullivan's private hospital, Pittsfield.

A Sanatorium for Consumptive Prisoners is also just completed at Rutland, and the Danvers Insane Asylum has separate cottages.

To this list may be added the Mattapan Day Sanatorium, maintained during the warm months by the Boston Association for the Relief and Control of Tuberculosis, and the Day Sanatorium of the Lowell General Hospital. A certain number of consumptives are also to be found in insane hospitals, almshouses and prisons. The general hospitals, as a rule, receive such only in exceptional cases.

Boston is soon to have a large addition to its facilities in the Consumptives' Hospital now about to be built at Mattapan. In establishing this hospital this city has set an example which every other city will do wisely to follow.

Besides what is being accomplished by the sanatoria and hospitals, much good work is being done by dispensaries and clinics. Among these are to be specially mentioned the tuberculosis clinic of the Boston Dispensary, conducted by Dr. Otis; the Out-Patient Departments of the Massachusetts General Hospital, Boston City Hospital and Carney Hospital, the Berkeley Infirmary and Trinity Dispensary. The tuberculosis classes have also proved extremely useful, and are well worth study and imitation. These are "for the home treatment by sanatorium methods of incipient and moderately advanced cases." Such are the Emmanuel Church Tuberculosis Class, conduced by Dr. Joseph H. Pratt; Arlington Street Church Tuberculosis Class, by Dr. N. K. Wood; Suburban Tuberculosis Classes, by Dr. John

B. Hawes, and the Cambridge Tuberculosis Classes.

The Boston Association for the Relief and Control of Tuberculosis, and similar organizations in Cambridge, Worcester, Springfield and Brockton, have also become important factors in this great and many-sided enterprise.

By these various means tuberculous patients are treated in their homes, are instructed in the methods of cure and prevention, receive the care of physicians and visiting nurses, some receive aid, and some are enabled to go on with their usual occupations.

All of this work is of great and far-reaching importance, but would be made infinitely easier and more effective if the hospital accommodations were sufficient for those cases in which the home conditions are unfavorable. That these conditions are unfavorable in a large proportion of cases we all know, and we also know how utterly inadequate are our 500 beds to the needs of the 10,000 advanced cases in the state.

In other states the lack of provision for advanced cases is as great as in our own, and in most cases greater. For incipient cases provision is becoming abundant. The sanatorium method, which was orginated by Brehmer in Germany in 1859, and which was first put into operation in this country by Trudeau at Saranac Lake in 1885, has been attended with such wonderful results that these institutions have rapidly multiplied. They are now to be found in nearly all of the northern states, New York standing at the head of the list, and the majority being private institutions. But the example of Massachusetts in building a state sanatorium has been followed, and there are now fourteen state sanatoria, completed or building, besides three others which receive state appropriations. The United States government has established sanatoria : at Fort Bayard, N. M., for the army; at Fort Stanton, N. M., for the Public Health and Marine-Hospital Service, and at Fort Lyon, Col., for the navy. These old military posts, no longer needed for fighting the Indians, are now attaining a higher usefulness in the war against consumption.

These various sanatoria, whether private, state or national, are almost wholly devoted to incipient cases. For advanced cases the provision thus far is mostly limited to large cities, and is made by the municipalities or by charitable and religious societies. Provision is also made in some states for the care of tuberculous insane and prisoners. The segregation of consumptives in the United States, however, is still in its infancy, and is very far from attaining that general and systematic character which alone can have any radical effect in suppressing the disease.

In Europe the conditions are much the same as here. The tuberculosis campaign on that side of the ocean is being pressed with extraordinary vigor. But it is the sanatoria for incipient cases which, at present, are receiving the most attention. Germany, the fatherland of Brehmer and Koch, leads the world in this respect, having over 100 sanatoria with 10,000 beds. Dr. Locke's recent article in the BOSTON MEDICAL AND SURGICAL JOURNAL gives a most interesting account of the "Crusade against Tuberculosis in Germany," and explains the part taken in it by the Workingmen's Insurance, the German Red Cross and the German Central Committee for the establishment of sanatoria for diseases of the lungs. But of all this great number of sanatoria, there are very few for advanced cases. The latest report I can find describes only 8, mostly small, but including one large one at Grosshansdorf, with 200 beds, built by the Workingmen's Insurance fund. In several German cities separate wards for advanced consumptives are provided in general hospitals, and much is also being done for this class through dispensaries and polyclinics, but the need of increased provision for these cases is deeply felt. As von Leube says, almost all of the existing German sanatoria are open only to a small minority of the cases, namely, the early incipient, whom he estimates at about 30,000; while for the advanced cases, of whom there are supposed to be 1,000,000, very scanty accommodations are provided.

In England, and elsewhere in Europe, the situation is much the same as in Germany. The care of early cases by sanatorium treatment is now chiefly engrossing the attention of the civilized world, while the advanced cases, far greater in number, and far more likely to spread the infection, remain in their homes, where they are receiving, it is true, an increasing amount of care through dispensaries and visiting nurses. This sort of care, however, cannot prevent the transmission of the disease to their families. The danger may be lessened, but in the home it is, in the great majority of cases, practically impossible to avert it.

The next step in the campaign will be to undertake the prevention of consumption by separating the sick from the well. For this, two things are chiefly necessary: first, to provide ample hospital accommodation for advanced cases; and second, to establish some systematic supervision over those who, for any reason, cannot be removed from their homes.

Fortunately, in Massachusetts, both of these wants are in a fair way to be supplied through the new laws but just enacted, one providing for three new sanatoria, and one for state inspectors of health. The commission recommended that these sanatoria should be inexpensively constructed, at a cost of about $500 a bed; and the appropriation is based upon this modest estimate, which is much less than the usual outlay for such institutions, most of them, including that at Rutland, having cost something more than $1,000 a bed. One of the newest in England, the King Edward VII Sanatorium at Midhurst, cost $1,000,000 for 100 beds, or $10,000 a bed, and is no doubt the most expensive of its kind. Since the construction of such sanatoria on a large scale now seems inevitable, a minimum of cost is a highly important desideratum, and if it can be demonstrated that a sanatorium embodying all the essentials, and not of too inflam-

mable materials, can be built for $500 a bed, the segregation problem will be materially simplified.

As we have seen, these three new sanatoria are likely to be filled up promptly with the overflowings of Rutland, — that is, with moderately advanced cases; but the great majority of consumptives will still be left, many of them unfit to be moved beyond the limits of their own town or city. For these, local hospitals are an urgent necessity, and no question can be more important than how to convince the public of their necessity and how to bring about their construction. The plan of construction is of minor importance. There will have to be an administration building, sufficient for future as well as present needs, about which may be grouped cheaply-constructed wards, cottages or shacks, which can be increased in number as needed. These should, if possible, stand in a plot of ground several acres in extent, and, while pure air and sunshine are essentials, the location should be near enough to a center of population to insure water-supply, drainage and fire protection as well as to permit frequent communication between the patients and their homes. In small towns a farmhouse may be utilized, while in larger towns and cities special buildings will be constructed or special wards added to existing hospitals, as at Fall River and Lowell.

As regards the size of these hospitals, a good rule might be to provide one bed for each thousand of the population, with the expectation of increasing in the future. At this rate it is evident that, in the smaller towns, only cottage hospitals would be required. A city of 100,000 population would have a hospital of 100 beds, costing, at $500 a bed, $50,000, and the annual cost of maintenance would be about the same as the cost of construction, or $50,000 a year. In cities and manufacturing towns, which have the largest ratio of consumptives, the hospitals will need to be larger in proportion to the population than in the rural towns.

It is to be confidently expected that philanthropic citizens, when they become convinced of the importance of this measure, will help to lighten the strain upon the public purse by donating land and buildings and contributing to a fund for their maintenance.

If all of these institutions are called sanatoria, it may be easier to induce patients to go to them than if they are called hospitals, though the word "hospital" has a far more cheerful sound in these days than it had a few decades ago.

What, then, can we, members of The Massachusetts Medical Society, do the coming year to help on the campaign against tuberculosis?

We have been considering two propositions: first, that we are a united body of missionaries who esteem it a duty and a privilege to aid any good cause whose object is to rescue the human race from the tyranny of disease; and, second, that we have arrived at an important crisis in the world's history, when a great discovery has shown us the possibility of annihilating tuberculosis. The truth of both of these propositions is so obvious that the only possible conclusion is that we must all, individually and collectively, launch ourselves into this campaign and determine that each year shall become memorable through the achievement of some notable victory.

Encouraged and stimulated by the brilliant successes of the past year, we can now look forward with new confidence and see more clearly where our duty lies.

The *prevention* of tuberculosis rises at the present time into special prominence, and it has been my endeavor to show that the ideal way to accomplish this is through the segregation of the sick. The new state sanatoria will greatly facilitate this separation, and it will be incumbent upon us to induce our patients to go to them, and to convince them that this is best for themselves and necessary for the protection of their families.

We can also agitate for the erection of additional local hospitals for advanced cases, and do what we can to interest people of wealth and liberality in this method of helping their neighbors. If this sort of missionary work is done only by a few of us, the results will be insignificant; but if we all take hold and do it together, enthusiastically and aggressively, a general and widespread interest will be awakened and we will have something to show for it a year hence.

But let me not be understood as urging activity in this one direction to the neglect of others. The problem is a complex one, and the campaign in many other directions is well under way. It is necessary to continue the attack with increased activity along the whole line. Here are some of the ways in which we can render efficient help:

We need to show our approval of the recent acts of the legislature by doing all we can to make them effective. To this end we must carefully comply with the law requiring notification of cases of tuberculosis to the board of health.

We can, whenever occasion offers, explain the importance of the anti-spitting law.

We can cordially co-operate with the state inspectors of health, who are to be appointed, and give them our support in the work they are to undertake, which is expected to result in a systematic organization of the war against consumption.

Moreover, we can lend our aid to the associations for the relief and control of tuberculosis; we can urge the appointment of visiting nurses, the establishment of day camps and dispensaries; we can take pains to see that the disinfection of houses after the removal or death of consumptives is thoroughly performed, and we can bring to the notice of manufacturers the admirable work which is being done in the factories of Providence, of Oxford and of Brockton.

Again, we can accomplish something in our district societies, by means of the committees on tuberculosis, which were appointed year before last, through the active initiative of Dr. A. T. Cabot, then president of the State Society, and now president of the State Committee on Tuberculosis. One way in which the work of these committees can be facilitated is by providing

them with funds for carrying on a campaign of education.

Having done all these things in the capacity of medical missionaries, there is one other thing which, as medical practitioners, we must not leave undone. We must seek out the incipient cases and send them to Rutland or some other sanatorium while they are yet in the curable stage. We can do this by being always on the watch for danger-signals, by making a careful physical examination in all cases of suspicious cough, of emaciation, of slight rise of temperature, of unexplained debility; by making early examinations of sputum; by not delaying to tell our patients of their condition and by carefully explaining to them how much better are the results of sanatorium treatment in an early than in a later stage. We must preach the gospel of outdoor life, and must insist that any of our patients who cannot go to a sanatorium shall have the open-air treatment at home.

And even this is not all. We need to keep constantly before the minds of the people that consumption can also be combated by improving the stock, by bettering the conditions of the working-people, by seeing that they are not deprived of light and air in their homes and the places where they work, and by preventing poverty, vice and intemperance. If those influences can be overcome which tend to sap the vitality of the race, infection will be less frequent, even though exposure continues.

Thus the problem of tuberculosis is found to involve the whole science of social economics, and to demand for its solution the combined efforts of all those who are striving in any way to improve the conditions of the human race. This is a holy war, and in it let us, Fellows of The Massachusetts Medical Society, do our full share of the fighting. Let us inscribe on our banners "Consumption not only can be cured, but it can be and shall be *prevented*."

ACIDOSIS.*

BY ELLIOTT P. JOSLIN, M.D.,
Instructor in the Theory and Practice of Physic, Harvard University.

THIRTY years ago this spring in Strasburg, Walter [1] published an account of a series of experiments on acid intoxication, which were more conclusive than those of previous writers. He discovered a marked degree of uniformity in the symptoms after the administration of hydrochloric acid to rabbits. If the quantity of acid inserted into the rabbit's stomach exceeded 0.9 gm. per kilogram in one day, death could be predicted within a few hours. The phenomena were ushered in by increased frequency of respiration. Each respiratory movement was deeper, more labored and accompanied with forcible heaving of the body walls. The animal lost the power of moving freely about and remained quiet in the position assumed. Having reached this stage one quarter of an hour intervened until death. The dyspneic character of the respiration now diminished, the blood pressure, which had been raised, fell and the heart's action grew scarcely perceptible, yet respiration invariably ended before the heart ceased to beat.

The administration of acid to dogs failed to produce similar symptoms, although double the quantity of acid was fed. Walter was so fortunate as to detect the reason for this immunity and to show that it lay in the capacity of the dogs to protect themselves by the formation of ammonia and the neutralization and excretion of 75% of the acid administered as an ammonium salt. This difference between the action of acid in dogs and rabbits has been shown by Winterberg [2] and others to be only relative, since rabbits can also protect themselves to a limited degree by the formation of ammonia, and on a proteid diet are less susceptible to acid poisoning,[3] while, on the other hand, dogs succumb with similar symptoms if the acid is injected into the veins. There is, in fact, general agreement from Walter's [4] time until now that symptoms of excitement with dyspnea, coma and death follow the intravenous injection of acid in rabbits, dogs and sheep.[5]

Much evidence has accumulated to prove that the cause of death is acidosis. The intravenous injection of an alkali simultaneously with even double or treble the ordinary lethal dose of acid prevents the occurrence of symptoms, and the introduction of an alkali, when death is imminent from acid poisoning, brings recovery.[6] It is, therefore, improbable that structural changes in the tissues have taken place, and indeed none such have been found.

The symptoms above recounted are not specific for any one acid, — hydrochloric, phosphoric, acid sodium phosphate and lactic acid.[7] They are distinct from symptoms attributable to poisoning with salts. They may resemble those of sodium nitrite and other drugs,[8] but the presence of such drugs in experimental acid poisoning has not been demonstrated.

The formation of ammonia is the response of an aminal to the injection of an acid. So far as I know, all agree that ammonia is a measure of acid metabolism, whether the acid is introduced into the body or formed within it.

Hallervorden [9] was able to show that the production of ammonia grew less when alkalies were injected. Ammonia is a "factor of safety" in our metabolism, and it is interesting to note that its neutralizing power is five times that of the common extraneous alkali — sodium bicarbonate.

Confirmation of acid poisoning is further found in the diminished power of the blood of these animals to neutralize acids. This can be estimated by the amount of carbonic acid present, because carbonic acid is displaced from its loose combination by any of the acids considered. Walter [10] showed in his fatal cases of acid poisoning in rabbits that the carbonic acid was lowered 90%,

* Read before the Association of American Physicians, Washington, D. C., May 9, 1907.

and Spiro [11] obtained fully as much reduction in dogs when he injected acid sodium phosphate intravenously. The direct titration of the blood after acid poisoning was undertaken by Spiro, who recorded a fall in alkalinity, from 169 mgm. NaOH to 73 mgm. NaOH per 100 cc. in dogs and a fall of 85 mgm. NaOH per 100 cc. in rabbits. Szili,[12] one of the latest investigators, obtained similar results. He also obtained a fall of 95% in the hydroxylion concentration of rabbits and dogs. The language of physical chemistry, however, often leads to confusion, because this apparently great change in concentration represents in 1,000 gm. of blood merely a fall in alkalinity from 51 ten millionths to 1.7 ten millionths grams. Unfortunately, the methods employed for the determination of the alkalinity of the blood are far from satisfactory and new developments may be awaited from the methods of Rzentkowski.[13] He has recently shown that the chief part of the blood's basicity is concerned with the albuminous portion of the red blood corpuscles. One gram of albumin of the red blood corpuscles corresponds to 4 gm. of albumin of the plasma in acid combining power.

Does man show an analogous condition to the acid intoxication of animals? Unconsciousness for a longer or shorter interval usually precedes death, even apart from those diseases in which there are obvious structural changes in the brain. A longer period of unconsciousness, coma, has long been known, but Kussmaul [14] called attention in 1874 to a distinct type of coma met with in diabetes. This was characterized by dyspnea — air-hunger — which preceded actual coma. The thorax expanded excellently in all directions, complete inspiration was followed by complete expiration. Congestion of the veins in the neck as well as cyanosis were absent. The contrast between the universal weakness and the strength of the respiratory movements was one of the most striking peculiarities of the picture. The pulse was often of extremely high tension at the onset of coma, but gradually wore out as it advanced. The impression left upon the observer invariably suggested some form of poisoning. Air-hunger, in the absence of cyanosis and of local and general convulsions served as a distinguishing feature.

Coma in diabetes is by no means an exceptional occurrence. The frequency with which it is met was recorded by Marsh,[15] in 1854 and that same year v. Dusch [16] differentiated it from uremic coma. Among 732 fatal cases of diabetes observed by various writers, death occurred as a result of coma in 53%. The type of coma in diabetes, which is most distinctive, occurs in what Naunyn [17] calls "pure diabetes," that form of the disease which runs its course free from complications in life and gross pathological changes after death. This occurs most frequently in the young. Any study of coma in diabetes loses its significance, unless this peculiar group is considered alone. Arterial changes are so universal in diabetes that coma of a cerebral or renal type is of most frequent occurrence. Such forms of coma have no connection with that under discussion, even though the urine may show a moderate acidosis.

Any comparison between Walter's coma of acid intoxication in animals with the dyspneic type of coma in man must not be carried too far. The cause in animals is of sudden onset, and occurs during health, but in man it is of gradual onset, increases in intensity and takes place in an individual debilitated with a long-standing disease. The main symptoms of restlessness, dyspnea and coma are common to each, and I am inclined to believe that the premonitory rise of blood pressure in rabbits will be found to have its counterpart in man.

Hallervorden's observations upon the excessive amount of ammonia in the urines of diabetics suggested to Stadelmann [18] that dyspneic coma presented an etiological as well as a clinical analogy to the coma of acid intoxication. Men, as well as dogs, increase the ammonia output after the administration of an acid, and in men, just as in dogs, the total amount of ammonia falls when alkalies are given. Until proof is afforded to the contrary, we are forced to explain an increased excretion of ammonia by the presence of acids somewhere in the body demanding neutralization. The experiments of Schittenhelm [19] would indicate that a relative increase of ammonia also had the same significance.

The excretion of ammonia in severe diabetics may increase from the normal quantity of about 1 gm. up to even 12 gm., and the cases are numerous in which 5 gm. are formed daily. The relative per cent of nitrogen in the form of ammonia to the total nitrogen rises much higher than was formerly supposed, not uncommonly reaching 25%, and in one of my recent cases was 41.2%, which is greater than in any case I have found reported. The patient is still vigorous. The total quantity of ammonia falls after the administration of alkalies, but as in animals, this goes on gradually. In rare instances the urine may be alkaline [20] and yet the ammonia may remain both actually and by per cent high. An alkaline urine, however, is no proof that the requirements of the body for alkalies are satisfied, but rather that the body is unable to utilize extraneous alkali in those tissues where the acid is formed. The total ammonia naturally falls in coma, if there is a diminished flow of urine. I have observed the ammonia fall from 38.8% a few weeks before coma to about 20% during coma, and Herter [21] has made similar observations. It is not strange that this does not take place in the death agony, and shows, as Müller suggested, that the ammonia represents the animal's power of compensation.

It is easy to measure how much acid is required to produce coma in a dog, but not so simple to determine from the blood and urine of man the quantity which has caused the same symptoms. Stadelmann attempted this task and found by estimating the acids and bases that although the urine was acid, bases were in excess, thus indicating the presence of an organic acid. He recognized the importance of this discovery and introduced the alkaline treatment of dyspneic

coma. Kulz [22] and Minkowski [23] independently discovered that the unknown acid was B-oxybutyric acid, although other organic acids, apart from di-acetic acid and its derivative acetone, were present in negligible quantities, just as they are in the urines of healthy people. The difficulty of estimating B-oxybutyric acid quantitatively and the ease with which its alleged derivatives, acetone and di-acetic acid, can be determined, diverted attention from B-oxybutyric acid as the chief cause of acidosis. Folin's [24] recently published method for the quantitative determination of acetone distinct from di-acetic acid only emphasizes this point. He shows that acetone can seldom constitute over 10% of the total acidosis. Acetone and di-acetic acid do not even vary relatively with the sum of the total acids.

The actual and accurate demonstration of B-oxybutyric acid as the chief alkali robber in dyspneic coma was made by Magnus Levy [25] in 1899. He was able to obtain by direct extraction from the urine of a child in dyspneic coma 4.5 gm. B-oxybutyric acid per kilo body weight, and from a similar though older child, during the day of temporary relief following coma, I obtained 3.5 gm. per kilo, or 180 gm. calculated as B-oxybutric acid from the excess of bases in the urine. Fully taking into account the difference in molecular weight of hydrochloric and B-oxybutyric acids, these quantities exceed the amount necessary to produce artificial coma in animals. Such large quantities of acid are only obtained from the urine during the day following coma. It is not the quantity of acid excreted, however, that does the harm, but rather that which is retained in the tissues. This may reach approximately 100 gm. during coma, according to Magnus Levy, and calculation shows that the lowering of the alkalinity of the blood corresponds with such quantities of acid. On the other hand, the body is provided with only sufficient alkali to neutralize some 80 gm. of B-oxybutyric acid apart from its capability of forming ammonia.

It is interesting to note that those clinical disturbances, indigestion, febrile affections, overexertion, which are apt to be followed in diabetes by coma, are all accompanied by acidosis.

Dyspneic coma is frequently encountered with smaller quantities of acid than those mentioned, and there are good reasons therefor. Acids are not excreted except as salts. Spiro showed this experimentally in rabbits and demonstrated a parallelism between the urine curve and the diminished alkalinity of the blood. When coma appeared the excretion of urine ceased, to recommence when soda was injected. It is only fair to state that in dogs an exact counterpart does not exist. It is a fact of clinical observation that such large quantities of B-oxybutyric acid as above mentioned are never obtained in long standing cases of diabetes, unless alkalies are given. Similarly large quantities of B-oxybutyric acid will not be excreted unless the quantity of urine is sufficiently great to hold it in solution. The per cent of B-oxybutyric acid in the urine did not rise above 1.5, even in my exceptional case, where the total excretion of acid reached 180 gm. in 24 hours. Outside of coma, Magnus Levy has never found it to exceed 0.6%. Larger quantities have often been reported in the literature, but they were not estimated by Magnus Levy's accurate methods. Since an abundance of alkalies and an abundance of urine are required for the elimination of large amounts of acid, it is not strange that debilitated diabetic patients excrete comparatively little acid in coma. It is equally obvious why injections of neutral salt solution and heart stimulants occasionally rescue a patient.

The dyspneic coma of diabetes cannot be cured by the injection of alkalies alone. The body must be in sufficiently good condition to rid itself of the acid, and even this is not all. Permanent recovery cannot take place without a continuous supply of alkali to meet the continuous formation of acid. The alkalies further must be offered the body in such a form that they can be utilized, not in the blood alone but in these tissues where the acid is produced. Temporary recovery from dyspneic coma is a most common incident. Because it is so common, but withal so temporary, many of us have felt it cruel to the patient to bring it about, and I have not forgotten the statement of the boy, whom I twice brought out of coma by injection of alkalies into the veins of both arms, that he was glad he had no other arm. The return to consciousness after the injection of an alkali is as striking a demonstration in man as the relief which follows a similar injection in an acid poisoned animal.

The reaction of the blood in diabetes confirms the view of an acid poisoning. Minkowski [26] found a diminution of the carbonic acid content of the blood of 40% in a non-comatose diabetic and of 90% three weeks later, when the same patient was in coma. Krauss,[27] Tambrey and Spriggs [28] record similar instances. Direct titration of the blood showed a lowering of the alkalinity in the hands of Krauss, Magnus Levy and Benedict.[29] It is to be regretted that Rzentkowski had no diabetic patient at his disposal. The experiments of Szili (*loc. cit.*) on the determination of the hydroxyl and acid ions of the blood showed a marked diminution of the alkalinity in the acid intoxication of animals, but Benedict (*loc. cit.*) failed to observe a similar change in diabetic patients. It is certainly open to grave question whether one could expect by his method in long standing cases of acidosis a result similar to an acidosis of animals running its complete course in an hour.

It is just half a century ago that Petters [30] held that acetone had causal connection with coma, but the experiments of Albertoni, Pissenti and Kussmaul so effectually disproved this possibility that the question was not again opened until in 1905 Grünberger [31] discovered its presence in the cerebrospinal fluid of a diabetic patient in coma. Until further experiments and clinical observations upon this point are carried out, it is improper to entirely disregard it, but it seems improbable that the presence of acetone in the

cerebrospinal fluid of diabetics is of especial significance. A specific action has also been ascribed to B-oxybutyric acid, quite apart from the influence it exerts as an acid. So far experiments have not been published which support this view, though Von Noorden [32] refers to such by Herter, in the fourth edition of his book. Von Noorden ascribes a certain part of the specific diabetic intoxication to the specific poisonous effect of B-oxybutyric acid, and he even considers the neutral salt of B-oxybutyric acid poisonous. I cannot reconcile this with his other statement that he knows many diabetic patients who have excreted 50 to 60 gm. acetone bodies daily for six years, nor do I find it consistent with the opinion expressed later on in the same volume, pp. 327 and 328, that he has had better results in the treatment of coma, presumably its preventive treatment, since he has used, at the recommendation of Naunyn and his school, very large doses of alkalies in place of the smaller doses which he previously employed, or, again, where he states that following the preference of Naunyn he has turned from salt and levulose infusions to an infusion of an alkali. Herter's observations and his opinion as communicated to this Association in 1900 also are strong evidence against any specific action.

The overwhelming amount of B-oxybutyric acid excreted by diabetics without discomfort makes it appear trivial to attempt the explanation of grave symptoms in many diseases by the coincident presence of a few grams of acid, or decigrams of acetone. Most of the observations on acidosis, other than in diabetes, have been based on qualitative tests alone, and even when these tests have been of a qualitative nature, they have almost without exception disregarded entirely the chief acid, B-oxybutyric acid. No instance has come to my observation of an excretion of more than 10 gm. of total acid in 24 hours. If the physiological chemists would only give us a short, accurate method for the determination of B-oxybutyric acid, we should hear much less of the harmful effects of acetonuria.

The treatment of acidosis in diabetes is too often symptomatic, despite Herter's warning given here in 1900. Etiological treatment is generally forgotten. As repeatedly emphasized by Naunyn, acidosis varies inversely with the capacity of the individual to utilize carbohydrates. A gain in the power of oxidizing a few grams of sugar avails far more than alkalies in overcoming acid intoxication. It is because the treatment of diabetes has been directed of late years toward improving this tolerance that the treatment of acidosis has also improved. Aside from general measures leading to this end, search has been directed for some form of carbohydrate which would be capable of oxidation in the diabetic body, and thus would promote the secondary oxidation of B-oxybutyric acid. For this reason lactose and levulose were tried, and recently Poulssen [33] has suggested the employment of the alga. The most hopeful outlook, however, is presented by Baumgarten's [34] discovery that the radicals into which the carbohydrate molecule is first split are capable of oxidation in the body. It is not unlikely that one of these radicals — gluconic, sucric, mucic, glycuronic and other acids — may eventually be available for the secondary oxidation of B-oxybutyric acid. Schwarz [35] indeed obtained favorable results with gluconic acid some years ago, but its expense so far has prevented its general use. Empirically such a body has been sought by Von Noorden in oatmeal.

The work of Eppinger [36] and Langstein [37] suggests that the use of amino acids may be better symptomatically than the employment of the simple alkalies. Eppinger (*loc. cit.*) prevented the appearance of coma in rabbits after the injection of acids by the simultaneous injection of the amino acids, and its protection apparently was not wholly due to the ammonia therein contained. On the other hand, the work of Embden,[38] Baer and Blum [39] warns us to proceed slowly with the employment of the lower fatty acids. The researches of Satta [40] and Borchardt [41] upon the acid-forming and acid-destroying components of fat and albumin must be further developed.

It is held up as a reproach against the alkaline treatment by Von Noorden that coma is not less frequent than before the days of alkaline therapy. It must be borne in mind that the possibility of death in diabetes from other causes, such as tuberculosis and sepsis, has greatly decreased during the last fifteen years. I think few will question the opinion that the duration of life of diabetics is greater than twenty-five years ago; as a result the disease uncomplicated reaches a greater degree of intensity before it claims its victim. Of this intensity acidosis is the expression.

SOME REMARKS ON NEPHROLITHIASIS.*

BY RICHARD FROTHINGHAM O'NEIL, M.D., BOSTON,
Surgeon to the Genito-Urinary Department, Boston Dispensary; Surgeon to St. Elizabeth's Hospital.

WITHOUT question stone is one of the most important surgical diseases of the kidney. The subject is so vast and the literature so voluminous that it is obviously impossible to more than mention many of the important features of the condition and to speak but briefly of some of the others. Of the etiology and physical properties of calculi I shall say little, since the discussion would carry us deeply into the problems of chemistry and metabolic changes, but I will endeavor to spend most of our time upon the symptoms and diagnosis of the condition.

There is a very short distance between the formation of gravel and the formation of stone in the kidney. When the soluble substances in the urine become precipitated and are washed out by the urinary stream, we have the condition of gravel. When, by means of mucus or some other organic material this precipitate becomes agglutinated, we have a small calculus, or at least, the nucleus for one, which grows as fresh crystalline deposits are made upon it. This calculus either passes down the ureter with more or less colic to become a bladder stone or be passed per urethra. Otherwise, it remains in the kidney, pelvis, calyces or substance, to grow and give rise to a variety of symptoms of a greater or less severity, but always sooner or later leading to destructive changes in the kidney tissue.

Morris divides calculi into primary and secondary. The former are met with when there is no infection present. Those formed from an acid urine being one or more of the following: uric acid, urates, calcic oxalate, cystine, xanthin and, rarely, indigo, those formed in an alkaline urine being of calcium carbonate and acid or basic phosphate of calcium.

Secondary calculi occur when there is change of reaction due to bacterial infection as in ammoniacal fermentation. They consist of the phosphates of ammonia and of magnesia.

In many cases a primary calculus becomes the nucleus for a secondary deposit because of the septic infection resulting from the irritation of the primary calculus. In point of size and number, calculi vary within a wide range, from very small stones which can readily pass through the ureter to those of enormous size, and in number from one to one or two hundred. In the calyces they may be slightly movable, in the pelvis they are, if of moderate size, much more freely so, and may fall into the ureter, blocking it. In either case they may take the shape of these cavities, sometimes filling them entirely and becoming firmly adherent which was the condition found in the present specimen. Those in the kidney substance are very prone to give rise to abscess formation with perinephritic rupture. According to Legueu and Albaran, bilateral stone occurs in nearly 50 % of the cases. Calculi may be met with at any age, but most commonly between twenty and forty. According to Morris the male sex is most often affected. Heredity seems to play a distinct part, particularly in the case of uric acid stones.

Briefly, the pathology of renal calculus may be divided into the aseptic and the septic changes due to their presence, which is the classification of the best authorities.

The aseptic changes.— There is, first of all, an irritation due to the passage through the kidney of a large amount of uric acid or calcic oxalate, etc., —in the precalculus stage; this irritation often becomes a catarrhal pyelonephritis which is soon followed by interstitial changes as well. The further change in the kidney may be brought about in two ways. There may be an atrophy of the kidney due to this calculus nephritis, or there may be destruction of the secretory tissue as a result of pressure from hydronephrosis, this latter occurring when the stone is of long duration and of sufficient size to entirely or partially occlude the ureter. There may also be an hypertrophy and induration of the perirenal fat, in some cases the kidney being replaced by fat tissue.

These aseptic lesions just mentioned, the nephritis, the retention of urine in the pelvis and the trauma of the stone, readily pave the way for septic infection which takes place through the blood or lymph stream or ascends the ureter from below. The colon bacilli is often the offending organism, the resulting lesion being pyelonephritis, pyonephrosis, nephritic and perinephritic abscess which may result through rupture in loin, groin, intestinal or thoracic fistulæ. Perinephritis often results in firm adhesions between the kidney and the surrounding tissue, making operation difficult. When pyonephrosisis is present the kidney is generally of good size and may consist of a number of different cavities, more or less shut off from one another, containing pus, purulent urine and calculi. When there is more or less destruction of the kidney on one side the process is a slow one and the other kidney generally becomes hypertrophied; it may, however, become the seat of a nephritis and the subsequent changes with resulting stone, like its fellow. Another remote result may be the sudden blocking of the ureter by stone; this may occur in both kidneys simultaneously or, as is most usual, in each successively. This is a grave condition and if not relieved will lead to ulceration and perforation of the ureter with the resulting infiltration and abscess and sinus formation, or death from calculus anuria.

The typical picture of renal colic, as formally described, with its pain, passage of stone, etc., is well known to all and needs no comment. It is also well known, however, that the typical picture is often absent and that renal stones present a great variety of symptoms, simulating other conditions.

Before going into the method of diagnosis, it might be well to consider the various clinical courses taken by renal stone.

1. They may present the typical renal and ureteral colic and be easily diagnosed, but in some cases renal colic closely simulates appendicitis,

* Read before the Providence Medical Association, April 1, 1907.

gallstones and other acute intra-abdominal conditions, and must be differentiated from them.

2. They may remain innocuous and unsuspected for years, giving no symptoms or slight ones which have been misinterpreted or long forgotten. The case I shall speak of is a marked example of this. These cases are, of course, always liable to sudden activity; although in a number of cases, stones have been found post-mortem that were unsuspected during life.

3. In some cases the symptoms may be referred entirely to other organs, as the bladder, the testicle, the uterus and ovary, —nothing being felt in the kidney itself. Frequent and painful micturition has often led to the diagnosis of cystitis and local treatment of the bladder with, of course, no relief. This is also true of other kidney lesions, as tuberculosis and neoplasm, both of which may, however, be complicated by stone. One should always have in mind the kidney as a causative factor of frequent micturition. Symptoms may also be erroneously ascribed to malposition of the uterus and diseases of the ovary. The cystoscope and x-ray have done much to clear up such cases.

The majority of cases, however, exhibit at some time certain typical symptoms, and careful attention to the history and painstaking examination of the patient will lead to a correct diagnosis. Among them are more or less frequent attacks of colic, due to the transient impinging of the stone in the pelvic end of the ureter with the pain in the loin or radiating to the testicle. Pain either in the kidney or referred to some other place is a frequent accompaniment of stone. It may be of all degrees of severity from an ache or feeling of lameness to pain of severe cutting or lancinating type. The referred or reflex pains have in part been mentioned and are described as the reno-renal reflex, pain in the other kidney, the reno-vesical, reno-testicular, etc. The pain is sometimes referred to the upper part of the thighs, the inside of the leg and the sole of the foot. The pain being largely mechanical and due to the actual bruising of the kidney by the stone is generally brought on or made worse by exercise or exertion and is relieved by rest.

Bleeding in stone generally takes place at some time or other in all cases. It is variable in quantity and as in the case of pain is generally increased by exercise and diminished by rest. This helps distinguish it from the bleeding of neoplasm. It is very apt to be associated with an attack of pain, the urine being dark or smoky for a few days following. The hemorrhage is rarely profuse, often microscopic. The bleeding of stone should be differentiated from the numerous other causes of hematuria.

Pus is present in the urine in many cases of calculus. Like the blood, it is due to the irritation of the stone; like it, also, it varies in amount according to the amount of inflammatory or destructive change there may be in the kidney. This may be all the way from a few microscopic leucocytes to the large amounts seen in pyonephrosis. A small or moderate amount of pus is rarely noted by the patient as the urine does not become offensive until pyonephrosis with decomposition is present, when the urine becomes very foul. He generally seeks advice because of the pain, colic or bleeding.

The diagnosis of renal stone not so many years ago was a matter of considerable difficulty and uncertainty, — most of the operations being for the drainage or removal of badly diseased kidneys. At present we are much better equipped and the diagnosis should be made early in most all cases.

The methods to be employed are as follows:

First, a careful family and personal history, particularly as regards pain or disturbances of micturition.

Second, palpation of the abdomen. There is often tenderness and muscular spasm over the affected kidney. Tumor is present in hydro- or pyo-nephrosis of any extent. Palpation will also help to eliminate any other intra-abdominal process.

Third, careful routine chemical examination of the urine and examination of the centrifuged sediment for epithelia cells, casts, blood, crystals, tubercle bacilli and the ova of parasites.

Fourth, cystoscopic examination. This is a most important proceeding in the diagnosis, particularly when there is doubt as to which side is affected; and in those cases before referred to with marked bladder symptoms, cystitis, bladder stone, or tumor may thus be eliminated. If the case is bleeding sufficiently at the time, the diseased side may be determined, also the presence of another active kidney. Much valuable information may be obtained from observation of the ureteric orifices, the presence of edema or inflammatory changes about one or the other of them or alteration in their size or shape denoting an existing or pre-existing inflammatory condition of the kidney. Pus in small amounts coming from the ureter is difficult to be sure of and the ureter catheter had better be employed. When present in any amount, however, as in pyonephrosis, it is readily recognized. Ureter catheterization, or segregation, the former much the more accurate, should be employed to ascertain the condition of the other kidney and obtain the separate urine for examination. A slightly bleeding kidney may thus be recognized. The ureters may also be explored for patency. With the wax tip bougie and the phonophore I have had no experience; good results, however, are reported in the use of both by those familiar with them.

Fifth, radiography. In spite of the fact that many unfortunate and embarrassing mistakes have been made in the past in the interpretation of plates, such as pleboliths, glands, night shirt buttons, etc., the technique is constantly improving and a good x-ray by an experienced operator is of the greatest help to the surgeon. A good plate should show the transverse processes of the vertebræ and the structure of the last two ribs; such a plate will show clearly ureteral and renal stones, and, according to expert radiographers, is also of negative value. The plates should show both kidneys and the entire course of both ureters.

According to Leonard nearly 50% of all calculi occur in the ureters. Bevan has mentioned two cases where the symptoms, *i.e.*, pain and tenderness, were on one side, the x-ray showing the stone in the opposite ureter where it was found and removed. The case I shall mention is of interest in this connection. He also points out that in cases where the x-ray is negative it may be impossible to differentiate clinically tuberculosis, hypernephroma, tumor, etc., from stone. A doubtful shadow in the ureter may be verified by passing a ureter catheter with a wire stylet, then having another x-ray and noting the relation of the wire to the shadow as has been done by Brown, Lewis and others.

Sixth. Cryoscopy. Ascertaining the freezing point of the blood is of importance in determining the amount of renal efficiency, — a lowered freezing point showing a lowered efficiency. The normal is ·56° C.

By the employment of some or of all of these methods a differential diagnosis from the various other conditions within and without the kidney can generally be made. These conditions have been briefly alluded to already and time will not allow me to take up the differential diagnosis any more in detail. They include tuberculosis, cancer, cystic kidney, tumor, abscess, floating kidney, etc. However, at times the x-ray will be negative or unsatisfactory, ureteral catheterization cannot be employed and the patient will present an array of symptoms that cannot be definitely interpreted. In such cases the condition can be diagnosed by exploratory operation only.

The treatment of stone may be divided into the expectant and the surgical. The former, according to Bevan, should be limited to the following conditions: (1) When the attacks are infrequent and mild and by x-ray the stones are of a size to be readily passed; but such cases should be kept under close observation; (2) where age or disease in other organs renders the removal of a stone more dangerous than its presence, and (3) where a stone is arrested in the lower end of the ureter when there is hope of assisting its passage by injection of oil or liquid vaseline into the ureter.

Without question surgical removal should be the treatment of most all cases of stone. When the diagnosis has been made early, operation should be most strongly urged as it is at this time that the most brilliant results are obtained with the greatest safety.

Nephrolithotomy is one of the most satisfactory of surgical operations when performed before the kidney substance has been injured or destroyed. When suppurative changes have taken place the indications for surgical interference are none the less imperative, and the course to be followed by the surgeon must be determined by the existing conditions in each case. Time will not permit a discussion of these conditions; suffice it to say that one of the following procedures is open to him: (1) He may cut down upon the kidney to explore it or evacuate any neighboring collection of pus. (2) He may drain the kidney either by opening the pelvis or by splitting the cortex. (3) He may remove the kidney at once or leave it for a subsequent operation.

In bad cases the latter is generally the operation of choice, being done when the patient is relieved of his sepsis, and is often necessary for the cure of chronic fistulæ. The treatment of calculus anuria is immediate single or double nephrotomy, as the case may be.

It is wise if possible to explore the ureter at the time of operation by passing a bougie down through it.

The mortality of nephrolithotomy in uninfected kidneys is about 3%. When septic processes have intervened it is said to be 10%, — a strong argument for early diagnosis and treatment.

In closing I shall refer briefly to a case which illustrates some of the points heretofore mentioned.

The case occurred on the service of Dr. C. L. Scudder, at the Massachusetts General Hospital, who operated and who has kindly allowed me to present it. I had the opportunity to see the patient several times in the Out-Patient Department and with Dr. Davis who made the cystoscopic examinations.

He is forty-one years old and gives the following history. No venereal diseases. He had suffered from attacks of pain in the left loin going down into the left testicle. The first attack occurred when he was sixteen and was constant and severe. He passed a very little blood at times and some gravel after the pain; once a stone the size of a pea. Four years ago he had a severe attack and thinks the stone passed into the bladder at that time. For the last three years he has had bladder pain and symptoms of vesical calculus. All of his previous symptoms were referred to the left side. Multiple vesical stones were readily detected with the searcher and he was recommended for operation for vesical calculi, with question of renal as well. He was cystoscoped later and two good-sized stones seen. An x-ray showed these very well and also a large shadow in the right kidney; nothing in left. His condition was not of the best, so it was decided to remove the bladder stones first and study the condition of the kidneys. The ureter could not be seen with any degree of accuracy at the first cystoscopic examination. A suprapubic cystotomy was done on February 18. He improved very much after this and a second cystoscopic examination was made. This showed apparently nothing, but pus coming from the right kidney and a normal efflux from the left. The left side was catheterized later and some pus was found coming from it as well. On March 7 the right kidney was explored and a large branched calculus was found and extracted with considerable difficulty, as it was intensely adherent. The patient did well. Some urine escaped for a time through the loin, showing that there was active renal tissue left, although at the operation the kidney did not look promising. The patient's condition would not have warranted a nephrectomy at the time.

The interesting points in this case are: (1) That a stone of this size could remain in a kidney so long a time without giving any hint of its presence, or without destroying the kidney entirely. (2) The absolute diagnosis by the x-ray and the confirmatory evidence of the cystoscope, I think without doubt, that the bladder stone came from the left kidney which at present, as far as can be told, is the seat of a slight pyelitis only.

NOCTURNAL PARALYSIS.*

BY ISADOR H. CORIAT, M.D.,
Second Assistant Physician for Diseases of the Nervous System, Boston City Hospital.

THE condition that I am about to report, at least in its complete type as here presented, is rather rare. In its slighter and more transitory form, however, it is fairly common in normal individuals. Wier Mitchell,[1] in 1885, first gave particular attention to this disorder, which he named night palsy or nocturnal hemiplegia. In his cases, however, the disorder assumed the type of a mere loss of sensation or a distinct loss of power in one limb or one half of the body, which was more or less protracted after awakening. The palsy always occurred between the half-sleeping and the half-waking state. The only cases reported in the literature in which the paralysis was generalized instead of local are those of Féré.[2] According to him, the disorder only occurs in subjects of neuropathic constitution and is closely related to the exhaustion paralyses. He interprets the condition as the result of a deficiency of physiological excitation affecting the motor and sensory functions. In connection with his cases he found some hysterical stigmata, such as color disorders and a contraction of the field of vision.

Féré reports two cases in considerable detail, and on account of their close resemblance to our observation a brief abstract of each will be given. The first case had marked heredity, suffered from chorea in childhood and finally experienced a severe emotional shock in the death of her husband. This was followed by depression, headache, nocturnal fancies and finally the peculiar condition of night palsy appeared. Towards six in the morning she would awaken, incapable of making any movement, the limbs felt numb, a portion of the limbs seemed wanting and the hands and feet felt as if attached directly to the trunk, analogous to the amputation neuroses. There was total inability to move until some one entered the room. The return of movement in the limbs was accompanied by painful sensations of numbness and prickling, and three hours usually elapsed before a complete restoration of motor power took place. In the second case the patient suffered from ophthalmic migraine for years and, as in the first observation, the general night palsy followed family bereavements. At first there was a generally increasing exhaustion and, finally, on awakening between the hours of four and six in the morning, the patient would find herself unable to move any of her limbs. At first this condition persisted for a few minutes only, then it gradually became prolonged to an hour, during which period there was a loss of consciousness of the entire body. After each attack the gradual return of power was accompanied by the same painful paresthesias as in the first case. Both patients recovered under general hygienic and tonic treatment. My observation follows:

* From the Neurological Clinic of the Boston City Hospital.

[1] Wier Mitchell: Nervous Diseases, 1885.

[2] Ch. Féré: A contribution to the pathology of night; nocturnal paralysis, Brain, xii, pp. 308-325, 1890.

Mrs. B. B., aged thirty-one, first came to the Neurological Clinic of the Boston City Hospital on Dec. 28, 1906, in the service of Dr. Morton Prince. The family history was negative and there was nothing of special interest in the personal history excepting a somnambulistic episode at the age of thirteen, in which she went to the kitchen, filled a teakettle with water and then suddenly awoke with no memory for her actions. In 1903, shortly after the death of her second child, the patient awoke one night from a sound sleep with a sinking sensation and a feeling of inability to move her limbs. This paralysis she described as being complete, with an inability to move any muscle, even the eyelids. After remaining in this condition for a few minutes she became fully awake and conscious, with a cessation of all the symptoms except a feeling of exhaustion, which continued throughout the morning. She had a similar attack the following night and on successive nights for a month, each attack being accompanied by cardiac palpitation, but unassociated with any particular sense of fear. These attacks became less frequent and after a short time completely disappeared. About a year ago, however, without any known cause, the attacks re-appeared and have occurred every night since, with an especially severe attack every Monday night, for which the patient can offer no explanation. During all this period her general health has remained fair. At present she will awaken in the early morning with a choking sensation and a feeling of suffocation, with palpitation of the heart and complete inability to move the body. The hands are usually clasped and the arms extended above the body. During the attacks she is fully conscious, knows what is going on about her, but is unable to open her eyes or to move her limbs even by the strongest exercise of the will. There is no amnesia or haziness of memory after each attack. The dreams are of an indifferent character. She will cry out for aid to move her arms or limbs, but until such aid is given she is unable to make any muscular movement whatever. The attacks usually last from two to five minutes before aid is given. She has no idea of their duration if she were unaided. The physical examination is negative, except a floating right kidney and a complaint of an occasional occipital headache. There are no hysterical stigmata.

Psycho-analytic methods yield the following interesting data concerning the attacks: They began about three months after the death of her second child, who died on a Monday afternoon under distressing circumstances. This acted as a strong emotional shock. Although the child had been ill for three weeks with pneumonia, yet his sudden death was unexpected. On this particular Monday afternoon the patient was alone and was holding the child in her lap. He suddenly reached the arms above the head, showed a general tremor, then became rigid and immediately expired. It will be noticed that the position assumed by the patient in her nocturnal paralytic attacks exactly resembled that taken by her child at the time of his sudden death and, furthermore, the worse attacks always occurred on Monday, the day of the week on which the child died. The coincidence is too pertinent and marked to be called accidental, and it seems, therefore, that we are probably dealing with a recurrent mental state originating in a sudden and distressing emotional shock.

The treatment consisted of waking suggestions

applied by means of a fictitious magnet (tuning fork) and directed toward a complete cessation of the attacks. This was given three times a week, and during the first month only seven attacks of palsy took place, whereas previous to treatment they had occurred every night. These attacks, too, were much lighter; she was able to come out of each voluntarily and to move the paralyzed limbs. As there have been no attacks since, a period of several months, it can be safely assumed that the patient has entirely recovered.

Féré's explanation of the condition is vague and unsatisfactory. Dr. Prince has suggested that the state is analogous to the temporary general palsy that is sometimes observed in patients during and after being awakened from a deep hypnosis.

With entire restoration of the personal consciousness a general paralysis may persist, as in a case which he informs me he has now under observation. In this case the palsy persists some fifteen or twenty minutes, is difficult to dispel and is associated with a general anesthesia. In one of my cases this post-hypnotic palsy persisted for fifteen seconds and the condition in every particular resembled that described in our observation. From recent researches on the various states of dissociated consciousness the interpretation is a very pertinent one. It seems to arise on a neuropathic soil and to follow a strong emotional shock. This is seen in Féré's cases and in our observation. Manacéine [3] has observed a cataleptic condition in different muscular groups in the half-waking or hypnagogic state, the limbs remaining in the strained position in which they are placed for a long time. She considers this half-waking condition as a natural hypnotic state. From the clinical history of our case the disorder can be interpreted as not only closely related to this post-hypnotic palsy, but also as a hypnagogic motor repetition of a previous strong emotional episode. In other words, we are dealing with a recurrent mental state whose chief manifestation is in the motor mechanism. We know how easily sense deceptions can arise in this dissociated hypnagogic condition, and in our case the dissociated complex assumed the picture of general but temporary nocturnal palsy without any concomitant hysterical symptoms. The condition, however, may occur as a momentary sensation in normal individuals, and only when it becomes prolonged and oft repeated can it be considered as having assumed a pathological aspect. The fact of complete recovery by psychotherapeutic methods speaks for the purely functional nature of the disorder.

MEDICAL COLLEGE OF THE UNIVERSITY OF MANILA.—The new medical college of the University of Manila, which will be opened early in September, will pay special attention to tropical diseases. The Philippine government has appropriated $62,500 for the expenses of the first year of the institution.— *Science.*

ASSOCIATION OF AMERICAN PHYSICIANS.

REPORD OF THE TWENTY-SECOND ANNUAL MEETING HELD AT WASHINGTON, D. C., MAY 7, 8 AND 9, 1907.

(Continued from No. 1, p. 25.)

OBSERVATIONS REGARDING THE HYGIENE OF MEDICAL CASES, PARTICULARLY IN HOSPITAL WARDS.

DR. D. L. EDSALL, Philadelphia, reviewed a number of groups of ward infections, part already recorded, part not published, and offered recommendations regarding points in ward hgyiene. He referred particularly to superinduced gastro-intestinal symptoms in typhoid fever patients and to high percentage of typhoid infections among nurses. Statistics showed that in three well-conducted hospitals the percentage of typhoid infections among nurses is 8 to 9 times as high as in the surrounding population. In one especially well conducted hospital typhoid infection among the patients in the wards is 2½ times as frequent as in the remainder of the city. Milk experiments had shown that marked abdominal symptoms may be produced by bad milk, due to infectious organisms present. The author had noticed on four distinct occasions foul, offensive diarrhea in several patients simultaneously. These he considered are due to secondary intestinal infections. A study of 2,600–2,700 consecutive cases of typhoid fever in the Episcopal Hospital, Philadelphia, treated in twenty-seven months, showed a very definite grouping of cases of hemorrhage and perforation. These groups occasionally coincided with the outbreaks of diarrhea. Based upon these data the author recommends more rigid technique in methods of prevention in hospitals. Milk should be pasteurized, unless well certified. There should be a special diet nurse. Sterile applications should be used in handling the mouths of typhoid patients and should not be passed from one patient to another. Bedpans and urinals should be sterilized, as well as their contents. Instructions to nurses should be more stringent.

DR. VICTOR VAUGHAN, Ann Arbor, mentioned the studies in typhoid during the Spanish War. Shakespeare, in a study of 4,000 carefully, observed cases, found 60% due to contact infection, and concluded that the fly was less active as a carrier of infection than had been previously held.

DR. KOBER, Washington, explained the large number of infections among nurses as due in part to the fact that persons between the ages of twenty and twenty-five were most susceptible to typhoid. The importance of milk as a carrier of typhoid infection was suggested by the relative number of epidemics in England and America as compared with the Continent; 90% of typhoid epidemics reported are in England or America, where raw milk is used. On the Continent, where raw milk is rarely used, only 10% of the epidemics occurs. In Washington 50% of typhoid is attributed to milk infection.

DR. PARK, New York, referred to mild epidemics of diphtheria in Children's Hospital, New York, due to carelessness of nurses. He mentioned a typhoid epidemic due to an infected ice-box. He had observed diarrheas produced by special types of milk.

DR. E. G. JANEWAY, New York, emphasized the importance of better care of nurses. Nurses were overworked. They should be allowed more rest. He had seen outbreaks of erysipelas checked by thorough cleansing of the ward. Recently in New York a cook

with typhoid infection without symptoms infected several families — 11 persons in one family, 5 in a second and 2 in a third.

Dr. Abbott, Philadelphia, mentioned an experience in Philadelphia during the winter of 1906–7. One of the men on hospital staff acquired diphtheria; he was isolated until cultures were several times negative. After one week's vacation he returned with a slight coryza. All the patients with whom he came in contact became infected; large numbers of organisms were found in his throat.

Dr. Northrup, New York, said that the watchword must be "eternal vigilance." He referred to the infection of two room-mates with typhoid. They drank distilled water, drank no milk, ate no lettuce nor other uncooked vegetable. The glass jar in which the distilled water was kept gave abundant growth of typhoid organisms.

Dr. Solis Cohen, Philadelphia, referred to the experience of the Presbyterian Hospital; there had been gradually an isolation, in separate wards, of cases of erysipelas, typhoid, pneumonia, owing to the numerous infections when any two varieties of cases were kept in the same ward; patients with transmissible diseases should be in separate wards for these diseases.

Dr. Edsall, in conclusion, agreed that separation should be as complete as facilities allowed. He had not intended to minimize contact infection. Eternal vigilance was most important. Too much responsibility should not be given to the nurse, for accurate investigation would often detect irregularities.

ANTITOXIN AND POST-DIPHTHERITIC PARALYSIS.

Dr. N. J. Rosenau and Dr. J. F. Anderson, Washington: Dr. Rosenau read this paper. All the experiments reported were on guinea pigs. The results, however, might be directly applied to man, as diphtheria and post-diphtheritic paralysis in man and in the guinea pig run an almost identical course. Guinea pigs were treated with a toxin-antitoxin mixture of such strength as to cause no death from toxemia, but paralysis in the second and third weeks and death from paralysis on the twenty-third or twenty-fourth day. To all guinea pigs the same dose of toxin-antitoxin was given. The effects of subsequent administration of antitoxin was tested with the following results: All controls died on the twenty-third or twenty-fourth day. Two hundred and fifty antitoxin units given 24 hours after the primary injection prevented death; 250 antitoxin units given 48 hours after the primary injection did not prevent death; 1,000 antoxin units given 48 hours after primary injection prevented death. Repeated small doses, beginning 24 hours after primary injection, resulted in recovery; repeated small doses, beginning 48 hours after primary injection, resulted in two recoveries, one death; repeated doses, beginning on fourth day — recovery in 1 — modified the course, but did not prevent death in the remainder. The authors conclude that unless seen early patients must be given very large doses, if post-diphtheritic paralyses are to be prevented; that after the development of the paralyses antitoxin treatment seems useless.

EFFECTS OF EGG-WHITE AND ITS SPLIT PRODUCTS UPON ANIMALS. A STUDY OF SUSCEPTIBILITY AND IMMUNITY.

Dr. Victor C. Vaughan and May Wheeler, Ann Arbor. Dr. Vaughan read this paper. For several years he had studied the products obtained by splitting up various proteid molecules. Proteids used had been bacterial, vegetable and animal. All might be split into poisonous and non-poisonous parts. Injections of the non-poisonous parts of B. coli and B. typhosus proteids induced immunity to the respective organisms. About two years ago egg-white was split into poisonous and non-poisonous parts. Drs. Rosenau and Anderson had found that one injection of blood serum produced practically no symptoms in animals, but that if this was followed by second dose serious symptoms, even death, might follow. Such experiments led the authors to try the effect of injections of the non-poisonous part of egg-white on animals. They found that the injection of non-poisonous portion of egg-white sensitizes the animal to the poisonous portion, as well as to the whole egg-white. It does not sensitize the animal to the non-poisonous part. This may be given in successive and increasing doses without producing untoward symptoms. By precipitation of an aqueous solution of the non-poisonous portion with absolute alcohol, two products are obtained which, injected separately, did not sensitize the animal; if they are injected together, however, sensitization takes place. The symptoms produced in sensitized animals by injection of the toxin portion are peritoneal irritation, partial paralysis, clonic convulsions and death. Guinea pigs sensitized require unusual amounts to end fatally. The following explanation is proposed: the body seeks to protect itself from foreign substances. When egg-white or its non-poisonous portion is injected, the body elaborates a new protecting substance in the form of a specific enzyme, capable of splitting this one proteid. To the first dose reaction is slow, the proteid is slowly split up and toxic symptoms are not produced. In the interim, a large amount of this enzyme is formed and stored as zymogen in body cells. On the second injection a large amount of this zymogen is liberated at once, the egg-white is very rapidly split up into poisonous products which are so quickly absorbed that grave symptoms of poisoning are produced. It is probable that this phenomenon is similar to that which occurs when animals are sensitized with the non-poisonous portions of the typhoid or colon bacillus and later inoculated with the living organism.

A REVIEW OF THE EXPERIMENTAL BASIS OF THE OPSONIC PHENOMENON.

Dr. Eugene L. Opie, New York, gave a short review of the development of the opsonic phenomenon. Metchnikoff, twenty-five years ago, had observed that avirulent anthrax organisms were more actively taken up by the phagocytes than the virulent ones. He interpreted this observation as an education of the phagocytes. Wright and Douglas, from test-tube experiments, found that Metchnikoff had underestimated the serum, that in the absence of blood serum phagocytosis was very slight or absent. They found that this applied to many, possibly all, bacteria, namely, that the normal blood serum so modifies bacteria that they are really ingested by phagocytes. The author had found that saprophytic organisms require opsonins to fit them for phagocytic ingestion. Marchand had further found that bacteria of high virulence are but little subject to phagocytosis and that because opsonins fail to activate. Denys and Le Clef, twelve years ago, found that the serum from rabbits' highly immunized streptococci possessed to a high degree the power to promote phagocytosis. Independently Wright and Douglas found the same, and further, that this increased phagocytosis was due to increased opsonic power of the blood serum. They found on inoculation a negative followed by a positive phase in opsonic power. They considered that low opsonic power probably precedes injection and observed that the fluid of the local lesion had lowered opsonic power, that opsonins are specific. The author had found that the fluid from the peritoneal cavity of an animal dead of infection with staph-

ylococcus aureus had no power to opsonify staphylococcus aureus. He had found, further, that in fluid brought out by turpentine application, there was a loss of opsonic power as the fluid changed from serous to purulent and concluded that presence or absence of opsonic power is an inaccurate measure of the grade of infection. The opsonic power of normal blood was subject to such variation that the estimation of opsonic index was inaccurate.

THE OPSONINS IN TUBERCULOSIS.

DR. E. R. BALDWIN, Saranac Lake, reviewed his work on opsonins in tuberculosis. In early experiments he found that serum from animals immunized to tubercle bacilli possessed high agglutinative, but low opsonic, power. Results were unreliable, due to clumping of organisms. He found that tubercle bacilli treated with serum of high opsonic power show greater virulence, more rapid spreading, when inoculated into animals (apparent enhancement of virulence). He offered the explanation that the phagocytes became overladen with the sensitized but still living bacteria, and after wandering from some distance from the point of inoculation break down; the bacteria set free start new foci. In summarizing his results with the technique of the opsonic test he concluded that he, at least, had been unable to obtain accurate enough results to use for diagnostic purposes or as a control to inoculations.

THE OPSONIC INDEX IN CERTAIN ACUTE INFECTIOUS DISEASES.

DR. LUDWIG HEKTOEN, Chicago: Dr. Herrick read this paper. In pneumonia the opsonic index was usually low during the course of the disease, rising after the crisis. Charts were exhibited indicating the variations in opsonic index during the course of scarlet fever. Individual normal variations have been found to be very small — .9 to .11. In nearly all cases of scarlet fever the index to streptococcus was below normal, rising above normal as recovery starts in and remaining about normal during convalescence. Complications were accompanied by depressions in streptococco-opsonic index. These results indicated that the streptococcus is present from the start in scarlet fever. Cases of scarlet fever were now being treated with streptococcus vaccines. In erysipelas, the opsonic index, low during the height, rises as the temperature falls. In diphtheria, antitoxin does not influence the opsonic index. The author suggested that injections of dead bacteria might help in promoting disappearance of organisms in the throat. In acute scarlatinal otitis media suppurativa, pseudo-diphtheria bacillus had been found as the predominating organism. The opsonic index toward this organism was low during height of disease, rising as discharge lessened. In typhoid and paratyphoid infections, opsonic index was low during the height of fever and during relapses, rising during convalescence. The author concludes that the opsonic index is of importance as a diagnostic and prognostic sign.

A SUMMARY OF THE STUDIES ON OPSONINS CARRIED OUT AT THE ROCKEFELLER INSTITUTE.

DR. V. H. SCHRORER, New York: Dr. E. L. Opie read this paper. The studies were concerned chiefly with the opsonic index in erysipelas and with the treatment of erysipelas by injections of killed streptococci. Preliminary tests to determine normal variations and accuracy of method showed variations between .5 and 1.7. Composite charts of results were shown. In erysipelas individual variations were great and often corresponded little with the clinical course. Sometimes the index was high when lesions were extending. In general, the index was low at the start, rose for the first three days and then fell. The increase corresponded with the progress of the disease, the fall with its decline. Therapeutically, vaccines prepared from streptococci isolated from wound infections and cases of erysipelas were administered in fifty cases. No definite conclusions could be drawn from the results. In a comparison with two other series of cases treated in the same hospital, but in different years, with antistreptococcic serum and local measures respectively, the duration of cases treated by vaccines equalled that of cases treated with antistreptococcic serum, but in both it was two days shorter than in cases treated locally. Conclusion reached was that from individual cases very little indication may be obtained as to progress of disease through the opsonic index.

A SUMMARY OF WORK ON OPSONINS AT THE JOHNS HOPKINS HOSPITAL.

DRS. L. F. BARKER and R. I. COLE, Baltimore: Dr. Cole read this paper. Attempts were made to produce high grades of opsonic power. Rabbits treated intraperitoneally, intravenously and subcutaneously with killed streptococci showed indices very little higher than controls. There was one exception. Dr. Klien obtained a very high index in rabbits treated with typhoid bacilli. Serum of those rabbits diluted 1-1000 possessed opsonic power equal to that of normal serum. The bactericidal power was augmented to the same degree. The relation between bactericidal and opsonic substances had not been determined. Like Simon and others, they found opsonins non-specific. Vaccines were employed in fifteen cases of gonorrheal arthritis and several cases of glandular and joint tuberculosis. It was the impression of the authors that the cases did somewhat better than those treated otherwise, although they advised caution in laying too much emphasis on the results in so small a series of cases. They conclude that as a guide to the administration of vaccines, the opsonic index is subject to too great variations to be relied upon.

A SUMMARY OF THE STUDIES ON OPSONINS CARRIED OUT UNDER THE AUSPICES OF THE COMMISSION FOR THE INVESTIGATION OF RESPIRATORY DISEASES OF THE NEW YORK BOARD OF HEALTH.

DR. HERMANN M. BRIGGS, DR. WM. H. PARK and DR. NATHANIEL B. POTTER: Dr. Park presented the chief results of this work. They consider the opsonic index an approximate and not a real index of opsonins in the blood. They found it impossible to reduce the limits of error as low as .8 to 1.2, as proposed by Wright. They find opsonins specific. After inoculations the negative and positive phases were not constant. As a test of vaccine treatment the opsonic index was of little value, giving often less accurate indications than did clinical symptoms. Charts to illustrate this point were presented. The conclusion was that no new era has been introduced in medicine, but that some good may be hoped for from vaccines.

DR. POTTER gave the results of his experience with opsonins. He found wide normal variations in the index of serum toward tubercle bacilli and staphylococci. Several cases of acne had been treated by staphylococcus injections, but without definite results. Two cases were reported: One of otitis media, in which streptococcic vaccines were of no benefit; the second a case of abscess, from which a streptococcus and a bacillus were obtained. The patient developed a septicemia with an index of .73. Vaccination with the streptococcus obtained from the patient with otitis media were followed, after the second injection, by a

virtual crisis. He predicted a promising future for the use of vaccines.

DR. NORTH, New York, reported the results of simultaneous estimations in ten different laboratories in various parts of the country. The purpose was to test the accuracy of the method. Serum was drawn in New York on Monday morning, sent to the various laboratories, so that all estimations might be made on Tuesday afternoon. The organisms used were staphylococci and tubercle bacilli. The patients whose serum was used were normal patients and patients with staphylococcus and tubercle bacillus infections. The average number of bacteria per leucocyte in 100 leucocytes was estimated. The results from the various laboratories were shown on a series of charts. Variations were between 40% and 200%.

DR. T. M. ROTCH, Boston, showed charts representing the effects of lumbar puncture and antitoxin injections upon the opsonic index. In cases treated by vaccines he had apparently found benefit.

DR. L. F. BARKER, Baltimore, said that opsonins had suffered from over-exploitation at the beginning. Tuberculin had a similar career, soon fell into desuetude and is now coming back. Vaccine therapy should not be coupled with opsonic technique. One of the most important results has been the transference of immunity problems from the laboratory to the patient.

DR. ROSS, of England, who has been a co-worker with Dr. Wright for two years, spoke enthusiastically in favor of the opsonic theory and the opsonic technique. He called attention to the difficulty of mastering the details of the technique, suggesting that it would take time for workers in this country to be sure of their results. It had been certainly demonstrated that the opsonic power is low in disease and rises with cure; that a negative phase occurs with untoward symptoms. This has been very clearly shown, *e. g.*, in cases of tuberculous cystitis. After two years of unceasing toil, the speaker has reduced the error to 10%. Under vaccines he had seen the cure of tuberculous dermatitis, adenitis, cystitis, iritis and empyema, furunculosis, sloughing abdominal wounds, and with cure, an increase in opsonic power. He pinned his faith to vaccine therapy and the opsonic theory.

DR. WEBB, of England, who had been a co-worker with Dr. Wright for one year, expressed himself as fully in accord with Dr. Ross.

DR. OPIE regarded the discovery of Dr. Wright as the introduction of a new era in the study of phagocytosis, since it showed the necessity of the serum for phagocytosis.

DR. PARK considered that vaccines have made acne curable, mentioning two cases which had resisted treatment, but recovered under vaccines.

DR. POTTER said there was promise of good results from vaccine therapy, and referred to the experience of Dr. Trudeau with tuberculin.

DR. NORTH believed that at present, for American laboratories at least, estimation of opsonic indices is subject to too great possibilities of error to be trustworthy, inasmuch as the average variation in ten laboratories was 50%.

THIRD DAY, THURSDAY, MAY 9.

ON THE PATHOLOGICAL ANATOMY OF LYMPHOSARCOMA.

DR. W. G. MACCALLUM, Baltimore: The present classification of Hodgkin's disease, lymphosarcoma, round-celled sarcoma, leukemia, chloroma, myeloma, was unsatisfactory. Through ignorance of etiology it was based on mode of growth, histological picture and blood picture. Sternberg's was the best recent classification. A study of a series of cases of lymphosarcoma showed a fairly definite histological picture, such as had been described by Kundrat and others. This, together with the mode of origin, distribution and extension, and with examination of the blood, made it possible to arrive at a definite diagnosis of the condition. Specimens were passed about showing types of lesions, the mode of distribution; specimens of two recent cases involving the lungs were exhibited. The question as to whether lymphosarcoma is tumor or inflammation must be left open for the present.

DR. CHRISTIAN, Boston, in discussion, held that the differentiation of the conditions under discussion was not on a sufficient basis.

DR. WHARTIN, from the study of 30 cases, concluded that there were many border-line cases.

DR. WRIGHT held the same view. A recent case at the Massachusetts General Hospital, which was histologically Hodgkin's disease, was clinically a mediastinal tumor.

DR. MACCALLUM replied that he had never seen a case which was histologically Hodgkin's disease, without the typical distribution of Hodgkin's.

CHYLOUS ASCITES AND CHYLOUS PLEURISY IN A CASE OF LYMPHOCYTOMA INVOLVING THE THORACIC DUCT.

DR. GEORGE DOCK, Ann Arbor, reported a case which showed clinically one large and several small tumor masses in the abdomen, chylous exudate in peritoneal and pleural cavities, moderate enlargement of superficial lymphatic glands and increase of lymphocytes in the blood. At autopsy the diagnosis was made of lymphocytoma. A tumor of the mesentery involved the thoracic duct, which was 4–8 cm. in diameter, without lumen. There were sarcomatous growths in lungs, liver and kidneys.

DR. MACCALLUM, of Baltimore, in discussion, referred to a case which resembled lymphosarcoma, with lymphatic leukemic changes in the blood; a second case similar to Dr. Dock's of lymphatic leukemia, with enlarged glands, which involved the thoracic duct; a third case, in which blood showed for years 90% of lymphocytes, enormous swellings of glands, with autopsy diagnosis of lymphosarcoma.

DR. WARTHIN, Ann Arbor, mentioned 4 cases of lymphosarcoma, which became leukemia. Of 37 cases of Hodgkin's which he had studied, some were of large-celled type, others of type resembling lymphosarcoma. He considered them all to be overgrowths of parent cells of leucocytes, "leukoplastomata."

A DIAGNOSTIC SIGNIFICANCE OF THE IODINE REACTION OF THE LEUCOCYTES.

DR. IRVING P. LYON, Chicago (read by title).

MULTIPLE MYELOMA: THE HISTOLOGICAL COMPARISON OF SIX CASES.

DR. HENRY A. CHRISTIAN, Boston, had studied six cases of multiple myeloma, with a view to determining their relation to one another and to a possible ancestral type of cell in the bone marrow. He showed on the screen photographs illustrating his paper. The cells of myelomata had been supposed by different observers to come from premyelocytes, myelocytes, lymphocytes, plasma cells or erythroblasts. All agree that they originate in the bone marrow. The study of the six cases showed tumors characterized by similar high degree of cellularity and by cells of only minor variations. The nature of this cell type had not been determined. It much resembles the plasma cell, but presents certain differences. There was no evidence of erythroblastic origin.

THE HISTOLOGICAL LESIONS IN EXPERIMENTAL GLANDERS. FROM THE LABORATORIES OF PATHOLOGY AND BACTERIOLOGY, McGILL UNIVERSITY.

DR. C. W. DUVAL, Montreal, reported the results of histological study of experimentally produced glanders. He showed lantern slides to illustrate the characteristic lesions. Histological changes were found to fall into three classes, — exudative, proliferative, degenerative. They varied directly with the virulence of the organism. Slides were shown to illustrate fibrin thrombi in the spleen; chronic proliferative changes in the adrenal, with necrosis, surrounded by epithelial cells; focal necrosis in the liver; tubercles in the lungs; giant cells and proliferative changes in tunica vaginalis of guinea pigs; myocardium of rabbits with focal collections of lymphoid and plasma cells; giant cells in endothelium of blood and lymph spaces; tubercles in spleen; degenerative changes in inner zone of media caused by killed bacteria.

DR. MACCALLUM, Baltimore, referred to a case of experimental glanders in man accidentally produced. In this case there was a caseous pneumonia, from which pure cultures of the organism were recovered. In places there was complete necrosis.

THE ANTAGONISTIC ACTION OF ALCOHOL AND CARBOLIC ACID.

DR. A. E. TAYLOR, Berkeley, Cal.: Alcohol was commonly considered as antagonistic to the action of carbolic acid. The following method of testing the matter was employed. A yeast tolerant to alcohol in concentration of nearly 15% was selected. This was placed in a standard solution of sugar; to this was added carbolic acid and alcohol in varying strengths. The carbonic acid evolved was measured as an index of the activity of the yeast, and it was found that the alcohol exerted no direct antagonistic action toward the antiseptic action of the carbolic acid. The author considers that alcohol acts merely as a solvent to carbolic acid and not as an antagonist.

DR. SOLLMAN, Cleveland, had observed that in experimental application of carbolic acid to the skin, followed by alcohol, the alcohol had apparently only a solvent action. In the stomach alcohol promoted absorption, though probably entirely apart from its action upon the carbolic acid.

DEMONSTRATION OF LARGE PHAGOCYTIC CELLS FROM THE CIRCULATING BLOOD.

DR. H. A. CHRISTIAN, for DR. F. VAN NUYS, Boston, passed about photographs of some large phagocytic cells found in the blood in a case of aortic insufficiency, chronic bronchitis, with indefinite tumor symptoms. There was no autopsy. Great variations in the blood count.

DR. CABOT, of Boston, referred to a case of aortic regurgitation, no tumor, no autopsy; leucocyte count high — 200,000 per cmm., from the ear, while count from the finger was only 10,000. He found that great variations in the count were due to clumping of leucocytes.

UNCLASSIFIED FEVERS.

DR. JAMES TYSON, Philadelphia, passed about charts and histories of a number of cases which were difficult to classify. They did not correspond with the typical picture of typhoid fever, influenza, malarial fever or other fever due to discoverable causes. He suggested that the Association might well take up the study of such cases in order to find if possible a proper classification.

A CONTRIBUTION TO THE STUDY OF LONG-CONTINUED FEVERS.

DR. H. C. MOFFITT, San Francisco, reported a case of long-continued fever and discussed the differential diagnosis. The patient was a woman over forty-seven; lues thirteen years before; cough every winter for ten years; appendix operation eight years before; attacks of abdominal pain suggesting cholelithiasis. Examination showed: old process at apices; pupils irregular, slow reaction to light; heart dilated, systolic murmur; no glands; spleen never palpated; abdomen distended, no tenderness; no pigmentation. Possibilities in diagnosis were: syphilis of liver, abscess of liver, lymphosarcoma, typhoid, malignant endocarditis, hepatic fever, pyelitis, tuberculosis. Treatment with mercury and iodides, later arsenic and x-ray, were unavailing and death occurred. Autopsy diagnosis was lymphosarcoma of one retroperitoneal gland, near right kidney, multiple nodules in liver.

DR. CABOT, Boston, in discussion, said that in the Massachusetts General Hospital, over 90% of all fevers of more than two weeks' duration were typhoid, sepsis or tuberculosis.

DR. STENGEL, Philadelphia, mentioned a case of long-continued fever, with a mass in the abdomen found at operation to be tuberculous retroperitoneal glands. Arteriosclerosis might also be a cause of long-continued fever.

DR. S. W. MITCHELL, Philadelphia, suggested that long-continued fever might be due to a disturbed heat regulatory mechanism; there might be a subnormal temperature following attacks of lumbago.

DR. GEORGE DOCK, Ann Arbor, reported a case of long-continued fever which eventually proved to be a case of syphilis.

DR. WM. THAYER, Baltimore, referred to two cases of lymphosarcoma involving the liver, and to the case of a trained nurse who had sweats, high fever, jaundice and enlarged liver, which proved to be one of carcinoma of the liver.

DR. R. H. FITZ, Boston, spoke of a case not yet diagnosed, with enormously enlarged spleen, fluid in abdominal cavity, induration of liver, no increased leucocytosis. Professor Mueller considered it one of chronic tuberculosis with possibility of Banti's disease.

FURTHER STUDIES ON THE SPIRILLA OF RELAPSING FEVER.

DR. F. G. NOVY, Ann Arbor: Since the paper delivered at last meeting, showing the existence of two and possibly three distinct types of relapsing fever, several foreign workers had confirmed the specific differences between Spirillum Obermeieri and Spirillum Duttoni. The type of relapsing fever which occurs in India is probably equally distinct. It does not react to the serum produced by the previously studied types. Cultivation in vitro had not yet been successful. Cultivation had been accomplished, however, by filling collodion sacs with blood, inoculating, and placing in peritoneal cavity of the rat. No growth obtained when capsules were placed in peritoneal cavity of rabbits. After 70 successive passages through rats, attempts at growth in vitro failed.

ON THE MEASUREMENT OF FUNCTIONAL HEART POWER.

DR. RICHARD C. CABOT, Boston: Methods ordinarily employed for examinations for the heart — auscultation, percussion, radiography, study of pulse and blood pressure — tell but little as to the amount of power possessed by the heart. It was important to measure the strength of the heart muscle early in both organic and functional diseases. Many attempts had been

made to accomplish this. Chapiro and others had studied the difference in rate between lying and standing; after a study of 100 cases they found that this difference was diminished only in pronounced cases. More recently other methods have been tried. Of these the author had had personal experience with the following: Graupner's method, Herz's method and Levy's method. He had studied a number of cases with Graupner's method and obtained results which were promising. He showed charts and blood pressure during the tests. In cases of definite advanced disease of the heart the blood pressure curve was modified, the rise either much delayed or absent. Similar curves were obtained in cases of phthisis and arteriosclerosis, in which the usual methods would have justified the note, "heart normal."

OBSERVATIONS UPON CERTAIN REFLEXES, LOWERING BLOOD PRESSURE, WHICH ARISE FROM STIMULATION OF THE INFLAMED PLEURA.

DRS. JOS. A. CAPPS and D. D. LEWIS, Chicago: Dr. Capps read this paper. Experiments were undertaken to explain the untoward effects of intrathoracic operations — faintness, dizziness, low blood pressure, syncopy, collapse, intermittent pulse, even death — with negative autopsy findings. It was found that in healthy dogs irritation of the pleura by mechanical, thermal, chemical and electrical stimuli caused very little change in blood pressure. In dogs, however, in which an artificial pleurisy had been set up by turpentine injection, marked reflex changes were produced with blood pressure by irritation of the inflamed pleura. The changes were due to combined vagal and vasomotor action. They were checked by cutting the vagi, by administration of atropin, and lessened by adrenalin.

CLINICAL AND PATHOLOGICAL STUDIES OF ARTERIOSCLEROSIS.

DRS. W. S. THAYER and M. FABYAN, Baltimore: Dr. Thayer read this paper, which consisted of a clinical and pathological study of the radial arteries in 40 cases, with a consideration of the distribution of arteriosclerotic changes. In comparing clinical with histological findings it appeared that many radial arteries which were definitely palpable were histologically normal. Photographs illustrating the findings were passed about.

CEREBRAL TYPES OF ARTERIOSCLEROSIS.

DR. ALBERT STENGEL, Philadelphia, spoke of types of cerebral manifestations of arteriosclerosis. Convulsive attacks, sometimes followed by coma, had been observed, simulating closely uremia, but with negative urinary findings. A case was referred to of a broken-down old man with loss of compensation, with very atheromatous arteries, history of two previous attacks of uremic convulsions. Patient was in coma. Following cardiac and general stimulation recovered from coma; later relapse and died, without autopsy. Albumin was never found in his urine.

FURTHER STUDIES ON EXPERIMENTAL ARTERIOSCLEROSIS.

DRS. I. ADLER and O. HENSEL, New York: Dr. Adler, who read this paper, reported the results of experimental and statistical studies of arteriosclerosis in rabbits. Previous experiments had seemed to show that as a result of injections of nicotine into rabbits arteriosclerotic changes are brought about identical with those of man. In the present series a much larger number of observations were made, 90 rabbits being experimented upon, 52 of which received injections of nicotine; of these only 9 showed signs of arteriosclerosis. Rabbits treated with barium chloride and with lead fail to develop arteriosclerosis. The authors conclude that arteriosclerotic changes occur spontaneously in rabbits not experimented upon, probably as a result of disease or senility; that the injections may possibly serve to augment an existing or bring out a latent condition; that there is no evidence that the substances injected ever cause of themselves arteriosclerosis.

DISCUSSION OF ARTERIOSCLEROSIS.

DR. JACOBI, New York, said there is a great variation in the location of arteriosclerotic changes. He laid much emphasis on sudden change of temperament as an early sign of cerebral arteriosclerosis.

DR. WEAVER reported two cases, both men over seventy, one dead, one living, who had convulsions simulating uremia but with no albumin or casts in the urine.

DR. SAILER, Philadelphia, mentioned three patients who had uremic convulsions with negative urine who improved under mercury.

DR. W. S. THAYER, Baltimore, said that in most cases in which there was thickening of the radials there was also similar change in the aorta. He emphasized the fact that the regressive changes in the radials are accompanied by calcification — that they occur principally in the media; whereas changes in the aorta take place mainly in the intima.

TYPHOID AORTITIS.

DR. A. S. WARTHIN, Ann Arbor, said the early lesions of typhoid endo-aortitis had been little studied. He had studied two cases in which lesions in the aorta were well marked, and lantern slides were shown illustrating the lesions found. The author considered the lesion a forerunner of arteriosclerosis and emphasized the fact that it is primary in the intima.

THE MODE OF CLOSURE OF THE DUCTUS ARTERIOSIS AND ITS BEARING UPON THOMA'S THEORY OF ARTERIOSCLEROSIS. FROM THE LABORATORIES OF PATHOLOGY AND BACTERIOLOGY, MCGILL UNIVERSITY.

DR. OSCAR KLOTZ, Montreal. (Read by title.)

MOTOR INSUFFICIENCY DUE TO PERIGASTRIC AND DUODENAL ADHESIONS.

DR. FRANK BILLINGS, Chicago, said perigastric adhesions occur mainly with diseased gall bladder, surgical operations and gastric ulcer. Symptoms were those referable to the underlying cause and those primarily due to adhesions. Of the latter were depression after eating, abnormal amount of gas in the stomach. Examination showed diminished motility of stomach. In treatment it was important to keep in mind the patient, especially if neurotic. One man who had undergone 15 operations for adhesions recovered completely when treated for his nervous condition.

DR. MUSSER, Philadelphia, in discussion, reported a case of typhoid fever with cholecystitis; on subsidence of temperature vomiting occurred; adhesions were found involving duodenum and gall bladder.

GASTRIC DISTURBANCES ASSOCIATED WITH THE PRESENCE OF AN EXCESS OF ACID.

DR. JOS. SAILER, Philadelphia, reviewed the usual methods of determining total quantity of hydrochloric acid and spoke of the method proposed by Sahli, of passing flour and butter into the stomach and estimating amount by percentage of fat in the fluid recovered. His own studies with the method of using dilute ferrous sulphate showed the limit of error to be 50%. He summarized 715 cases, giving the results of stomach analyses.

ON THE LENHARTZ TREATMENT OF GASTRIC ULCER AND HYPERCHLORHYDRIA.

DR. S. W. LAMBERT, New York, spoke of the practical objections to the old method of treating these conditions, principally depletion of the patient. The Lenhartz treatment consisted in frequent small meals of easily digested food in gradually increasing amounts. Eight cases were reported with recovery in all but one. The writer found that this mode of treatment cured more rapidly than former methods and without depletion of strength.

DR. JACOBI, New York, reported good results from two-hourly feedings; he used calcine magnesia combined with alkalies seven minutes before meals to diminish the acidity.

THE EFFECTS OF NAUHEIM BATHS ON BLOOD PRESSURE.

DR. P. K. BROWN, San Francisco: Dr. Brown's studies show that blood pressure is raised by the Nauheim bath at temperature of 94° to 98°. This rise seemed dependent upon the presence of calcium chloride. There were exceptions; blood pressure was not raised in exophthalmic goiter, pericarditis with effusion, paroxysmal tachycardia, and marked valvular disease. It was especially valuable in chronic valvular disease, and in chronic and acute poisonings.

THIRD DAY, THURSDAY, MAY 9.

JOINT SESSION WITH THE AMERICAN PHYSIOLOGICAL ASSOCIATION.

ACIDOSIS.

DR. E. P. JOSLIN, spoke for the physicians, reviewing the development of the theory of acidosis. He spoke of the importance of ammonia increased in the urine in acidosis. The important acid eliminated is B-oxybutyric, "the great alkali robber" (Magnus Levy), which has reached 180 gm. in twenty-four hours. He referred to the studies on the blood, its reaction and its CO. 2 content. He discussed the cause of symptoms in diabetes and other conditions, taking issue with von Noorden, who holds diabetic coma due to the acid. He considered the treatment as hopeful. Important in treatment was the ingestion of a few grams of sugar, of more avail, the author thought, than much alkali.

DR. OTTO FOLIN, for the physiologists, presented a critical review from a biochemical standpoint, of the more important concepts in the theory of acidosis. He spoke of the development of knowledge concerning the relation between acetone, B-oxybutyric acid, and acetoacetic acid. He referred to the recent work showing that fatty acids are the chief source of this group of substances; also that in the splitting of fatty acids the break occurs at the third carbon atom — the so-called B-oxidation theory. A chart was shown illustrating this theory. He referred to the alkali in treatment of acidosis and to the difficulty of explaining its action.

DR. WENDEL, New Haven, spoke of the importance of the study of alkali loss and retention in diabetes and in other conditions. He referred to the work of Thayer and Hazen on calcium metabolism. He suggested that the ammonia production might be increased, giving rise to undue production of acid.

DR. L. F. BARKER, Baltimore, said that fatty acids are among the products of proteids; hence proteids may give rise to acetone bodies. He spoke of the remarkable adaptability of the body, which seems capable of using intermediary products of digestion for neutralizing excess of ammonia. He suggested that disturbance in specific oxidases might account for inability to break down B-oxybutyric acid. He mentioned Mueller's use of phenolphthaleine internally to indicate at once the point of alkalinity of the urine.

DR. THAYER, of Baltimore, reported a case of acid intoxication with diacetic acid in the urine, in a child, following operation, which improved under sodium bicarbonate.

DR. TAYLOR, Berkeley, Cal., spoke of the discrepancy between symptoms and amount of acidosis. In non-diabetic conditions most pronounced symptoms occur with small amount of acetone bodies in the urine. In diabetes symptoms of acid intoxication might be absent for months with large amounts of these bodies present. This suggested that other acids than those known may cause the symptoms.

DR. FOLIN, in concluding, admitted that other acids than the ones mentioned might cause symptoms. He took issue with the idea of derangement of ferment action in general, as too indefinite at present. He considered it an open question whether the acids are produced to neutralize the alkali or vice versa.

DR. JOSSLIN said, in conclusion, that coma might ensue if the diet were suddenly made carbohydrate free. Recent work had shown that the treatment of coma must be the same as formerly — administration of proteid and fat, no carbohydrates. He agreed with Dr. Taylor in the distinction between forms of acidosis.

Book Reviews.

Der Diabetes Melitus. By DR. B. NAUNYN, formerly Professor in Strassburg University. Second edition. Vienna: Alfred Hölde.

Professor Naunyn has made us all his debtors by supplementing his original monograph upon diabetes mellitus with a new edition. Like its predecessor, this volume holds its place as the foremost on the subject. This is not strange, for it is from the Strassburg school that so many investigators along this line have derived their inspiration. Although the book remains of the same size, the enormous amount of recent literature has been most painstakingly and critically reviewed, and thus replaces those portions of the work which, on account of their original character, were detailed at length in the first edition.

During the eight years that have elapsed since this appeared the doctrine of acidosis has found general acceptance, and the source of B. oxybutyric acid from the members of the fatty acid series with an even number of carbon atoms seems probable. Levulosuria, pentosuria, suprarenal and submaxillary glycosurias, the new views which have arisen concerning the pancreas on account of the part played by the islands of Langerhans, and the etiological importance of the various albumins, are subjects which all receive careful discussion.

The section on treatment has been enlarged, and convincing proof afforded of the desirability of the most careful attention to diet. Indeed, one must read Naunyn's book to catch the true spirit of the modern treatment of diabetes mellitus. The style is clear, terse and fresh from beginning to end.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 11, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

A MEDICAL MEETING IN TURKEY.

DURING the last week of this month a medical meeting will take place in Aintab, Turkey, which is the first ever held in that country. This meeting is another evidence of the progress of practical Christianity, since it has been planned by the American Board of Foreign Missions, in which is represented the only modern medical service of that country.

The need of such a meeting as this is likely to be is not to be questioned. It has long been a well-known fact that the Oriental is slow in adopting modern methods and that the loss of human life resulting from ignorance has been and still is appalling. It is, therefore, significant that the attempt is to be made in systematic fashion to spread the gospel of modern medicine in this somewhat benighted country. Delegates to the convention will naturally be in great part those who are working throughout the country as missionary physicians. A prominent Turkish physician, Dr. Altoonian, of Aleppo, is, however, expected to be present. Other delegates are expected from Van and Constantinople, separated by a distance of about eight hundred miles. Among these will be two Germans.

In matters of surgery the native profession in Turkey is peculiarly ignorant. The methods still adopted are both crude and cruel, and are often provocative of disease rather than curative. The native doctors will be welcome at the public sessions of the meeting, which are designed to give instruction, through illustrations and by other means, in matters relating to bacteriology and pathology. The general topics of the meetings, however, will cover a wide field, as, for example, cholera, typhus, pneumonia and malaria; the need of native trained nurses; cataract and its operations; x-ray work; scope of medical missions in promoting municipal sanitation and personal hygiene; hospital buildings and their plans. During the morning there will be clinics, operations and a demonstration of laboratory methods, and a certain time will also be given for recreation.

There can be no doubt that such a meeting will serve as an admirable object lesson to the native physicians who may be in attendance. It is equally evident that through these native physicians the practice of the country must ultimately be conducted. The few outsiders who may be there in the capacity of medical missionaries, or in other capacities, can do much by way of example and precept, but comparatively little by actual work. The campaign there as elsewhere must primarily be one of education. This, no doubt, will be a slow and difficult process, but it is evidently the only one, if the native population throughout the country is ultimately to be reached by modern medical methods. Such a meeting as the one to which we allude, and to which reference is made by Miss Frances J. Dyer, in the July number of the *Dietetic and Hygiene Gazette*, cannot fail materially to further the cause.

ACCIDENTS OF JULY FOURTH.

IN spite of the somewhat determined agitation against the careless use of explosives on the Fourth of July and the innumerable warnings, both from the professional and lay press, against the dangers especially associated with certain types of noise-producers, comparatively little progress apparently has been made in reducing the number of deaths and accidents. In Boston during the period from six o'clock on July 3 to midnight on July 4, fewer accidents were reported at the large hospitals than during the same period in 1906. Thirty-four were treated at the City Hospital this year, as contrasted with 42 last; 46 at the Relief Station, as contrasted with 51, and only 18 at the Massachusetts General Hospital, as against 40 in 1906. This showing is certainly gratifying and possibly bears some relation to the fact that only 150 arrests were made this year as compared with 383 last, for violations of the city ordinance in relation to the discharging of firearms and fire-crackers and the blowing of horns.

The compiled reports, however, tabulated by the Chicago *Tribune*, do not give the year throughout the country so good a record. At 3 A.M., the

second day after the Fourth, the *Tribune* had recorded 59 deaths and 3,807 injuries, a death-rate which was equalled, but not passed, in 1900 and 1905. The list of injuries is the longest as yet tabulated. Pittsburg apparently leads cities in the United States in the number of killed and injured, with New York second on the list. Up to 10 o'clock on July 5, fifteen violent deaths had been reported in the former city. As usual most of the casualties were due to carelessness in handling powerful explosives. There seems to be some slight improvement in the popular attitude toward the toy pistol. Figures compiled the day after the Fourth showed only 205 victims as against 304 last year. The results of injuries by toy pistols cannot, of course, be immediately known. It is altogether probable, however, that the protest against this form of enjoyment in the hands of the young has borne fruit and that the number of fatalities from tetanus will be smaller than heretofore. We should certainly have decidedly more encouraging figures in the coming years.

MEDICAL NOTES.

HERTER LECTURES. — According to the *Journal of the American Medical Association*, the next annual course of lectures on the foundation established by Dr. and Mrs. C. A. Herter will be delivered about the end of April, 1908, by Edward A. Schaefer, LL.D., ScD., F.R.S., professor of physiology in the University of Edinburgh, Scotland.

THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. — The Rockefeller Institute for Medical Research has adopted the following series of titles for its staff: Member, Associate Member, Associate, Assistant, Fellow and Scholar of the Rockefeller Institute, and has made the following list of appointments:

Simon Flexner, Member of the Institute and Director of the Laboratories (pathology); S. J. Meltzer, Member of the Institute (physiology and pharmacology); E. L. Opie, Member of the Institute (pathology); P. A. Levene, Member of the Institute (biological chemistry); Hideyo Noguchi, Assistant of the Institute (pathology); John Auer, Assistant of the Institute (physiology); Alexis Carrel, Assistant of the Institute (experimental surgery); J. W. Jobling, Assistant of the Institute (pathology); Nellie E. Goldthwaite, Assistant of the Institute (chemistry); C. M. A. Stine, Fellow of the Institute (biological chemistry); Donald Van Slyke, Fellow of the Institute (biological chemistry); Martha Wollstein, Fellow of the Institute (pathology); Maud L. Menten, Fellow of the Institute (pathology); Mabel P. Fitzgerald, Fellow of the Institute (bacteriology); Don R. Joseph, Fellow of the Institute (physiology); Benjamin T. Terry, Fellow of the Institute (protozoölogy); Bertha I. Barker, Scholar of the Institute (pathology); Thomas W. Clarke, Fellow of the Institute (pathology).

Grants to aid special researches have been made to the following: Robert M. Brown, New York; C. H. Bunting, Charlottesville, Va.; Katherine Collins, New York; Cyrus W. Field, New York; N. B. Foster, New York; Joel E. Goldthwait, Boston; Holmes C. Jackson, Albany; Arthur I. Kendall, New York; Waldemar Koch, Chicago; W. G. MacCallum, Baltimore; Wilfred H. Manwaring, Bloomington, Ind.; J. W. D. Maury, New York; F. G. Novy, Ann Arbor; W. Ophüls, San Francisco; Richard M. Pearce, Albany; H. T. Ricketts, Chicago; Hermann W. Schulte, New York; Charles E. Simon, Baltimore; Aldred S. Warthin, Ann Arbor; Francis C. Wood, New York.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 10, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 48, scarlatina 28, typhoid fever 12, measles 53, tuberculosis 38, smallpox 0.

The death-rate of the reported deaths for the week ending July 10, 1907, was 14.97.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, July 6, 1907, was 160, against 168 the corresponding week of last year, showing a decrease of 8 deaths and making the death-rate for the week 13.69. Of this number 90 were males and 70 were females; 158 were white and 2 colored; 94 were born in the United States, 61 in foreign countries and 5 unknown; 31 were of American parentage, 112 of foreign parentage and 17 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 53 cases and 3 deaths; scarlatina, 25 cases and 3 deaths; typhoid fever, 8 cases and 3 deaths; measles, 61 cases and 3 deaths; tuberculosis, 43 cases and 19 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 9, whooping cough 0, heart disease 24, bronchitis 3 and marasmus 1. There were 13 deaths from violent causes. The number of children who died under one year was 34; the number under

five years, 43. The number of persons who died over sixty years of age was 43. The deaths in public institutions were 65.

There was 1 case and 1 death reported from cerebrospinal meningitis during the week.

A Centenarian. — Michael Maloney died in Monson, Mass., July 2, at the reputed age of one hundred and two. He was a successful farmer in the town of Brimfield for forty years.

Experts for the Examination of Mrs. Mary Baker G. Eddy. — Judge Edgar Aldrich, of the Federal Circuit Court, has been appointed by Judge Chamberlain, of Concord, N. H., to take evidence as to Mrs. Eddy's competency to care for her property interests. Judge Aldrich has stipulated that in this task he have expert aid. Drs. G. F. Jelly, of Boston, and G. Alder Blumer, of Providence, R. I., were appointed to serve with him. Since this announcement was made, it has been stated that Dr. Blumer has declined to serve, because of absence from the country during the summer months, and that Dr. Jelly has accepted.

A New Danger from Arsenate of Lead. — It is reported that many cattle have died in Essex and Middlesex counties in Massachusetts, where arsenate of lead has been used in the attempt to destroy gypsy and brown-tail moths. The theory is that the arsenate of lead sprayed over the foliage and on the grass is a source of poison to the cattle who may be browsing. Naturally, precautions are taken to avoid this contingency, but the fact that certain cases have occurred should necessitate still greater care in the future. The possibility of the poison finding its way into vegetables designed for human consumption is a remote contingency, but one which should be borne in mind.

NEW YORK.

Summer Home for Sick Babies. — The summer home for sick babies connected with the Rockefeller Institute was opened for the season on July 1. The old Schermerhorn mansion, on the banks of the East River, which was included in the tract of land purchased for the Institute, has been fitted up for the reception of sixty patients, and infants from all over the city are admitted. Drs. Morden and Van Ingen are the attending physicians, and Dr. Linsly R. Williams is consulting physician. While the administration of the home is under the auspices of the New York Association for Improving the Condition of the Poor, all the expenses of maintenance are paid by Mr. Rockefeller.

Injuries by Firearms. — Despite the warnings of Police Commissioner Bingham against the illegal and indiscriminate use of guns and revolvers in the observation of Independence Day, and despite a large number of arrests for breach of the law, there were five persons killed, and the police reports show at least 126 injured in the boroughs of Manhattan and the Bronx from this cause. It is to be noted that a large proportion of those arrested for violation of the firearms ordinances were foreigners. Up to midnight on July 4, 367 casualties in all, due to pistols and fireworks of various kinds, were reported from the hospitals and by the police. Every hospital in the city which receives accident cases had its full share of them and the ambulance service was over-worked.

Report of Health Department. — The weekly reports of the Health Department show that during the month of June the mortality in the city represented an annual death-rate of 16.65, as against 17.49 in May and 16.00 in June of last year. Among the diseases in which there was a diminished fatality were the following: the weekly average of deaths from whooping cough decreased from 9 in May to 7.5 in June; the weekly average from cerebrospinal meningitis, from 22.25 to 14.25; from pulmonary tuberculosis, from 184 to 165.25; from acute bronchitis, from 19.75 to 13.75; from pneumonia, from 115.5 to 86.75; from organic heart diseases, from 145 to 141.25; from Bright's disease and acute nephritis, from 115 to 101; and from cirrhosis of the liver, from 21.25 to 16. Among the diseases which showed an augmented mortality were the following: the weekly average of deaths from measles increased from 18.75 to 29.25; from scarlet fever, from 21.25 to 26; from diphtheria and croup, from 34.5 to 38; from cancer, from 57.5 to 64.5; and from apoplexy, congestion and soften- of the brain, from 47.5 to 48.75. The special feature of the statistics of the month is the remarkably low mortality, for the season, from diarrheal diseases. The number of deaths from these was just about the same as in May, while in the last week of the month of June, when a somewhat notable increase is always anticipated, the deaths were considerably fewer than in any of the other weeks. In the week ending June 29, there were only 38 deaths (as against 166 in the corresponding week last year), while the average for the other weeks of the month was 61. During this week there was not a single death from diarrheal disease in the whole Borough of the Bronx, a most unusual circumstance.

Obituary.

RICHARD HENRY DERBY, M.D.

DR. RICHARD H. DERBY died at Litchfield, Conn., July 4, 1907. He was sixty-three years of age, having been born in Boston, March 12, 1844. His father was Elias Hasket Derby, of Boston, and his mother was Heloise Lloyd Strong, of New York. He was descended from good stock on both sides. His Derby forefathers, the well-known family of that name in Salem, Mass., were among the most prominent shipping merchants of their time in this country. During the Revolution they played a patriotic part, helping their struggling country with money, men and ships. One of them carried in his own vessel, the *Quero*, the first news of the Battle of Lexington to England; one of them owned the ship, *Columbia*, whose captain discovered and named the great Oregon River.

Dr. Derby graduated at Harvard College in 1864 and from the Harvard Medical School in 1867. He served the usual term as house surgeon at the Massachusetts General Hospital and then went to Europe to continue his professional studies. He there devoted himself especially to diseases of the eye. On his return home in 1870, he settled in New York and entered upon practice as an oculist. He was an active and very influential member of the staff of the New York Eye and Ear Infirmary and for some years had been the Senior or Executive Surgeon. He was a member of the New York State Charities Aid Association, of the New York Academy of Medicine, of the American Ophthalmological Society, and a trustee of the New York Institution for the Blind. At one time he was much interested in matters connected with quarantine, with the Health Department of the city of New York, and in the condition of tenement houses. He was a vestryman of Trinity Church in New York, which is a large owner of tenement house property, and was always interested in church affairs. For some years past Dr. Derby had been a member of the Advisory Board of the Health Department and in these several capacities had done much to combat the increasing spread of trachoma. He was for many years a member of the Century Club.

In summer he had been devoted to yachting and had cruised the coast many times from Long Island Sound to the British provinces. He was also fond of fishing and of botany and had given much attention to the trees and shrubs and wild flowers on the coast of Maine, especially as found at Islesboro, where of late years he made his summer home. His was a wholesome, helpful, useful life. He made and kept many friends in all classes of society and all walks of life.

Dr. Derby was married, in New York in 1877, to Sarah Coleman Alden, who died in Algeciras, Spain, last March. He leaves three sons, and a daughter who is the wife of Dr. P. A. Tucker, Professor of Chemistry at Columbia College. The oldest son, having the same name, follows his father's profession in New York.

8. HOELSCHER, J. *The Medicine and Surgery of Three Gastro-intestinal Cases.*
9. *BROWN, P. K. *Remote Effects of Tonsillar Infection.*

6. Bowditch and Griffin briefly summarize the results, so far as they have been traced, of cases discharged from the Sharon Sanatorium as "arrested" in the fifteen years ending with January 1, 1906. Of these 83% are known to be living and well, 3% were doing well when last heard from but have been lost sight of, and 13% have relapsed and died. Of the last 81 of these cases 95% have remained apparently well. The diagnosis in all cases was proved either by the finding of bacilli in the sputa, by the tuberculin test, or by the presence of marked signs in the chest which, combined with the history, made the diagnosis undoubted. These results are published as evidence of what can be accomplished in sanatoria, since these 160 cases occurred in a total of only 327 cases treated. Attention is called also to the educational value of such institutions, and of the dispensaries for the guidance of home treatment. In conclusion, however, it is stated with emphasis that the influence of climate is a factor, the importance of which must not be disregarded.

7. Soper describes a family epidemic of typhoid fever in which after investigating without result the commoner sources of infection, attention was directed toward the previous history of various members of the household. It was found that a new cook had come to the house about three weeks before the disease broke out and had left three weeks after the appearance of the disease. This woman was traced, and on investigation it was found that in the past ten years she had lived with eight families, and that in seven of these typhoid fever had occurred following her arrival. No history of illness could be obtained in her case, but on the strength of the occurrence of these epidemics the New York Board of Health sent her against her will to the Detention Hospital. Her blood was found to give a positive Widal reaction, and bacteriological examination of the fæces showed typhoid bacilli to be present in great numbers.

9. The pathologic conditions that appear as the late results of tonsillar diseases are discussed by Brown, who first remarks that the importance of this source of infection for heart disease has been pretty thoroughly exploited and that he has himself reported in a previous paper some typical cases and reviewed the literature. Since then he has observed recurrent endocarditis, chorea and muscular rheumatism occurring in certain of his old patients, and he considers that continued slight fever in children is probably a common result of tonsillar disease in San Francisco. A rather peculiar complication of pericarditis, pneumonia and lung abscess is reported. Nephritis after tonsillitis without rheumatism is, he thinks, a commoner complication than is generally supposed and has occurred four times in his cases. One of these, complicated by acute mania, is reported, as also one of fatal staphylococcic septicemia and one diagnosed as leukemia occurring in connection with, and presumably as the result of, tonsillar disease. The evidence, he thinks, clinical and experimental, tends to show that more and more connection is being established between the tonsillar cervical route and lung tuberculosis. Brown concludes with the statement: "In the study of portals of entry of disease into the human body, the pharyngeal and especially the faucial tonsils

have an importance not well enough recognized or understood, but increasingly appreciated in the light of each new clinical or experimental study." [F.W. P.]

5. LEDERER, E. J. *The Milk Supply of Vienna.*
6. *ROBINSON, W. J. *Pilocarpin as an Adjuvant in the Treatment of Syphilis.*

6. Robinson advocates the use of pilocarpin as an adjuvant to mercury in cases in which the system has become saturated with mercury, and it has ceased to have the desired effect. The glands continue hard, swollen and tender, and stomatitis is marked. Gastro-intestinal, hepatic, renal and skin activity have been neglected. The pilocarpin causes the elimination of mercury that was stored up in the salivary glands and acting as a toxic body. In the bowels and kidneys the elimination has been too great for the organs and the pilocarpin causes the skin to act and carries the mercury to the seat of the skin lesions. The author recommends its use in doses of two to eight milligrams two or three times a day, without other drugs. It is of much value in secondary manifestations, and is a most remarkable glandular eliminant. In some cases supersaturation with mercury produces intolerance of the drug and the use of pilocarpin for a short time will enable us to resume mercury with excellent effect.

8. SABEL, S. O., and SLATTERLEE, G. R. *Acute Lymphatic Leukemia Clinically Suggesting a Myelogenous Origin.*

1. Deaver does not consider it likely that trauma is ever the exciting cause of appendicitis in a previously normal appendix. He does believe, however, that in an appendix containing a latent abscess, or adherent to the peritoneum over the ilio-psoas muscle from previous inflammation, trauma may cause the lighting up of an acute process. There are 130 cases in the literature where this is supposed to have occurred. The mortality is high in such cases, largely because of the difficulty of diagnosis.

1. Erb reports a case of acute lymphomatosis with a leukemic blood picture occurring in connection with a streptococcus sepsis. The autopsy showed an exquisite lymphomatous metaplasia of all the blood-forming organs. Streptococci were found in the blood and various glands just before death, their point of entrance being apparently necrotic tonsils. The blood picture was 2,250,000 reds, 26,700 whites, 45% hemoglobin. The white cells were made up of 91% of lymphocytes, the majority of which were large with faintly staining nuclei. The patient, a young man of twenty-eight, previously well, was sick only a little over one month, septic symptoms, fever and chills being first noticed. Erb does not agree with Türk that, in these cases, the sepsis is the primary infection, but thinks that until experimental proof is offered to show that a lymphomatosis can develop on the tissue changes produced by a previous septic infection, we must consider the leukemia as primary and the sepsis as a terminal infection. An interesting finding in this case was, that in a hemorrhagic area in a testicle, the nature of which, whether septic or a leukemic infiltration, could not be determined, the lymphoid cells in the interstitial tissue were phagocytic; it would seem that in acute leukemia the lymphoid cells acquired the faculty of phagocytosis, which is certainly not a function of normal lymphocytes.

9. *CLOETTA, M. *Digitoxin and Digalen.*
10. *CRÄMER. *The Effect of Nicotin, Coffee and Tea on the Digestion.* (Concluded.)

1. Report of four cases of chronic poisoning with manganese, occurring in the manufacture of permanganate of potash. The poisonous agent is supposed to be manganous oxide. The symptoms consist of paraplegia with peculiar spastic paretic gait, psychic changes and sometimes alimentary glycosuria. The course was tedious with slow improvement under general measures.

3. Grassmann reveiws the subject of the effect of nicotin on the heart and vessels. Most common is a cardiac neurosis, the "tobacco-heart." Nicotin injected into animals is capable of producing similar lesions of the arteries to those of adrenalin, and there is little doubt that the long continued excessive use of tobacco can produce arteriosclerosis in man. The best clinical proof of this is the fact that intermittent claudication, a disease in which arteriosclerosis plays an important part, is rare in non-smokers, while two thirds of Erb's cases used tobacco to excess. Experimentally, nicotin is known to cause contraction of the peripheral arteries and rise of blood pressure, and this if long continued would favor the production of sclerosis. Very important is the fact that tobacco may cause attacks identical in appearance with true angina pectoris, and this without the intervention of arteriosclerosis. The prognosis of such seizures, provided the use of tobacco be discontinued, is much better than in ordinary cases of angina.

4. Eichelberg gives mortality statistics of 1,574 cases of delirium tremens from the Hamburg-Eppendorf hospital. Excluding those with pneumonia, the death-rate was 2.4%. This very low mortality is attributed chiefly to the early use of cardiac stimulants in appropriate cases; indeed, Eichelberg advises now the use of digitalis from the beginning in all cases, a method by which Ganser in a large series has obtained a death-rate of .9%.

5. The bacilli of paratyphoid fever, of meat poisoning and of mouse typhoid are apparently identical. It has been claimed, however, that the last named is not pathogenic for man. Shibayama of Tokio brings evidence that this is not the case. In Japan pure cultures of mouse typhoid bacilli, mixed with meal, are extensively used to

exterminate mice, being given out by the government for that purpose. Shibayama reports four epidemics due to the accidental contamination of food with such mouse poison. An acute gastro-enteritis resulted like that of meat poisoning, and death occurred in several instances. The bacilli of mouse typhoid were recovered both from the food and from the stools of the victims.

6. Previous researches by Uffenheimer had shown that the intestinal tract of the newborn guinea pig differs from the other laboratory animals, in that it will not allow the passage through either of bacteria (the tubercle bacillus excepted) or of albumin. Further investigations by this author showed that this protection against bacteria was due to the much greater bactericidal power of the blood serum. This is due to an abundance of alexin or complement. In order to show that the protection against invasion was dependent on the presence of alexin, he experimented with adult rabbits whose alexin had been removed by a special method (anchoring of the alexin by injection of red corpuscles of the goat). Animals treated in this way and then receiving injections of bacteria by enema, showed after a few hours bacteria in all the viscera, whereas the organs of the control animals were sterile.

7. Report of a case of acute neuritis affecting the facial, both auditory, and the abducens nerves; recovery. The involvement of the cerebral nerves in neuritis is rare, in spite of the frequency of the peripheral form.

9. Polemic against Kiliani.

10. Digestion experiments by Crämer, carried out in test-tubes, showed that the addition of black coffee, tea, nicotin or extract from tobacco smoke to digestive mixtures seriously interfered with the action of pepsin. The patent nicotin-free cigars had, if anything, a more deleterious effect than ordinary cigars. The amounts added were calculated to correspond to a moderate use of the above drugs. An experiment on a very moderate smoker, showed that a single heavy cigar with each meal was enough to cause motor insufficiency of the stomach and a spastic condition of the intestine. Crämer's clinical statistics showed that the abuse of tea, coffee and tobacco was very frequently met with in various affections of the gastro-intestinal tract, especially in hyperacidity, impaired gastric motility, and spastic constipation. The abuse of alcohol was less frequent and apparently of less importance in the etiology of these affections.

6. SACHS, H., and TERUUCHI, Y. *The Inactivation of the Complement by the Withdrawal of Salt.* (Continued.)

2. Bloch has devised a method by means of which tubercle bacilli in urinary sediments may be demonstrated by inoculation in the short time of nine days, instead of thirty to sixty days, the usual time of an inoculation experiment. The washed sediment is injected subcutaneously in the thigh of a guinea pig, and the corresponding glands in the groin are at the same time crushed with the fingers. After nine days, if tubercle bacilli were present in the sediment, they may be found in large numbers in the excised inguinal glands.

5. In Caro's case an acute Graves' disease ended fatally soon after excision of $\frac{7}{8}$ of the goiter, with hyperpyrexia and collapse. The urine shortly before death showed marked toxicity, the excised thyroid contained a very large proportion of iodine. There were present considerable enlargement of the liver and spleen, and of the cervical glands, with 60% of lymphocytes in the blood; these features are interpreted as a pseudoleukemic state induced by the acute intoxication with thyroid secretion.

15. Storp reports a case of a man twenty-one years of age from whom 510 cm. of small intestine were removed during the extraction of a spindle-celled sarcoma of the mesentery. An immediate end-to-end suture was done, following which the patient made an uninterrupted recovery. On several occasions tannigen or opium was necessary to correct a tendency to diarrhea. In four weeks the patient had gained four kilos in weight and digested ordinary diet without difficulty. The bowels moved normally once or twice a day. About two months later, however, pain and a tumor mass were again present, the condition being such that further operation was impossible. Twenty-two cases from the literature are tabulated, all illustrating the point that very long pieces of small gut may be removed without much disturbance of digestive functions. The longest resection reported is that of Nigrisoli, in which 520 cm. were removed, following which the patient gained 5.1 kilos in twenty-three days.

16. Nyrop reports fifty-four cases of gastro-enterostomy with an operative mortality of 3.7%. He then discusses in detail the causes which make a gastro-enterostomy unsuccessful, quoting freely from the literature, and giving in each instance the best recognized method of avoiding such causes. They are to be divided as follows:

A. Post-operative causes:
   1. Peptic ulcer of the jejunum.
   2. Spontaneous gastropexy.
   3. Secondary narrowing of the anastomosis.
   4. Chronic volvulus of the coils of small intestine.
   5. Diarrhea.
   6. Entrance of bile or pancreatic secretion into the stomach.
   7. Peritonitis.
   8. Hemorrhage from the wound.

B. Pre-operative causes:
   1. Poor general condition of the patient.
   2. Too great atony and dilatation of the stomach.

Nyrop insists that these last two factors are practically always the cause of the so-called "vicious circle," and that the technique of making the anastomosis is not responsible for its occurrence.

18. According to Joseph, who writes from the clinic of Professor Bier, the process of inflammation depends on two factors: (1) A harmful agent (bacteria, toxins, etc.), and (2) a blood capable of destroying this agent. If either of these factors changes, inflammatory phenomena disappear. If the infectious material is removed there is no longer inflammation; if the patient becomes pyemic, his blood, having lost the power of destroying these bodies (bacteriolysis, etc.), even a large amount of infectious material will not call forth inflammation. These same rules apply to stasis hyperemia. On the arm of a pyemic person, or when the infecting agent has been removed, the bandage causes only a purely static edema, a change in the blood content such as is seen when the normal limb is constricted. There is absent that peculiar reaction of the blood, due to capillary hyperemia, which Lexer calls an "erysipelatous redness," and which is to be considered a gratifying phenomenon, since it means that the blood is capable of destroying infectious material. By experiments Joseph has shown that

this capillary hyperemia is capable of removing much infectious material from the general circulation. The result to be most desired after the application of a stasis bandage is, therefore, an intense redness reaching up to the point of constriction, and only partially disappearing during the intervals when the bandage is loosened and the extremity elevated.

19. Federmann reports sixteen cases of perforated gastric ulcer. Five were moribund and no operation was done. Of the remaining eleven four were cured by operation. Of the seven post-operative deaths, three died of secondary abscesses; four of spreading peritonitis. Emphasis is laid on the fact that many of these cases through faulty or slow diagnosis reached the surgeon so late that his efforts were of no avail.

22. Martina reports the case of a woman of thirty-three years who had suffered for four years with what she considered stomach trouble. The disease began as a sudden severe pain in the region of the stomach, a little to the left of the middle line, occurring in the eighth month of her first pregnancy. There was no vomiting. The pain ceased after the birth of the child and did not recur for a year. There was no trouble with appetite or digestion at this time. With the occurrence of the second pregnancy the pain returned, and following this time increased in severity, being of a heavy, boring character. It was much less severe during the time when the stomach was empty, increasing quickly after eating. Gradually the diet became reduced to about one half liter of boiled milk per day; the weight was 15 kilos below normal. She had twice been treated for gastric ulcer without benefit. At operation the pancreas was found enlarged, of unusually firm consistency and with a nodular surface. The peritoneum covering the body and tail of the organ was split for a distance of 10 cm. The abdomen was closed with drainage. Convalescence was uneventful and when seen 2¾ years afterwards the patient was in perfect health without any digestive disturbances. [W. C. Q.]

Miscellany.

A TEMPERANCE BUREAU.

A SOCIETY has been formed in Boston, Mass., called the Scientific Temperance Federation, organized and incorporated by the laws of the state with power to hold real estate and receive donations and legacies. The purpose of this society is to collect and keep on file all books, papers, pamphlets, studies and data, concerning the physiological, chemical, psychological, social and economic relations of alcohol and narcotics and the allied evils which follow. Also to accumulate literature on insanity, crime, race degeneration and associated topics. This literature is to be filed, catalogued and placed where it can be made accessible to persons who wish to study it. The object is to form a great central bureau for the collection and dissemination of exact facts from the entire literature of the world, so that physicians, authors and writers may be able with little expense to go over the entire field of research on these topics. Its aim is also to enable every writer, specialist and original worker to have his conclusions put on file where they can be studied and examined and become of more practical service. A trained assistant will furnish abstracts and copies, and other data of all the literature on file and thus enable the student to determine what has been written. A membership fee will be charged, which will entitle one to abstracts, data and copies of future publication. Others not members will be charged research fees for copies and abstracts that may be called for. This society was organized in December, 1906, and already it has secured a very large collection of pamphlets and papers. This is an independent organization, with a distinct purpose of gathering facts on all sides of the question, and appeals to every student as a most practical agency for the dissemination of the exact facts. Hon. W. C. Lilley, of Pittsburg, Pa., is president, and T. D. Crothers, M.D., of Hartford, Conn., is chairman of the board of directors. Inquiries should be addressed to Miss C. F. Stoddard, 23 Trull St., Boston, Mass.

DR. WILLIAM K. OTIS.

AT the Annual Meeting of the American Urological Association, the following resolutions were adopted upon the death of Dr. Otis:

Whereas, in the death of Dr. William K. Otis, the American Urological Association has lost one of its founders and former officers, and a member whose genial personality made him beloved of all, and whose scientific attainments had placed him in the front ranks of his profession, therefore be it

Resolved: That this Association expresses its profound regret at the loss of so esteemed and valued a member and friend; and be it furthermore

Resolved: That these resolutions be spread upon the minutes of the Association, that a copy thereof be transmitted to the family of the deceased and that a further copy thereof be furnished the medical press for publication.

Signed:
FREDERIC BIERHOFF,
ORVILLE HORWITZ,
DESANTOS SAXE.

Correspondence.

ARABIAN SCIENCE.

ROXBURY, MASS., June 29, 1907.

Mr. Editor: I observe that Professor Osler, of Oxford, says, in a recent discourse, that the physicians of the Arabian school made no solid contributions to anatomy or physiology (JOURNAL, June 27, 1907). This is undoubtedly true, yet they made valuable contributions to science. Geber, eighth century, discovered arsenious acid and corrosive sublimate. Albucasis, twelfth century, discovered alcohol and the art of distillation. Alhazan, of Cairo, eleventh century, wrote a valuable treatise on optics and described the properties of lenses. Rhazes, of Bagdad, tenth century, gave the first accurate description of smallpox; Avicenna, eleventh century, of malignant pustule; Avenzoar, of Seville, twelfth century, of the itch. We owe to the Arabians the methodic use of opium as a remedy, which, though used by Dioscorides and some of the Grecians to a certain extent, was apparently unknown to the Galenists. They also used mercury, which was first made known to the Europeans as a medicine by the Moors and Saracens, was adopted by Guy de Chauliac and Paracelsus and formed the chief ingredient of the prescription sold by Barbarossa, the corsair of Mitylene, to Francis I to cure his pocks. We cannot date a letter without the Arabic numerals, or compound a salt without an "alkali," a purely Arabic word. Altogether we owe a good deal to the Arabians, which we ought not wholly to forget.

Yours respectfully,
EDWD. T. WILLIAMS, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JUNE 29, 1907.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED JUNE 26, 1907.

GASSAWAY, JAMES M., surgeon. Granted leave of absence for twelve days from June 24, 1907. June 21, 1907.

WHITE, J. H., surgeon. Granted leave of absence for seven days from June 8, 1907.

BILLINGS, W. C., passed assistant surgeon. Granted leave of absence for three days from June 27, 1907. June 25, 1907.

STIMSON, A. M., assistant surgeon. Directed to report to Chairman of Board of Examiners, Washington, D. C., July 18, 1907, to determine his fitness for promotion.

RUCKER, W. C., assistant surgeon. Directed to report to Chairman of Board of Examiners, Washington, D. C., July 18, 1907, to determine his fitness for promotion.

WARD, W. K., assistant surgeon. Directed to report to Chairman of Board of Examiners, Washington, D. C., July 18, 1907, to determine his fitness for promotion.

TRASK, J. W., assistant surgeon. Directed to report to Chairman of Board of Examiners, Washington, D. C., July 18, 1907, to determine his fitness for promotion.

ROBERTSON, H. MCG., assistant surgeon. Directed to report to Chairman of Board of Examiners, Washington, D. C., July 18, 1907, to determine his fitness for promotion.

STILES, CH. W., Chief, Division Hygienic Laboratory. Directed to visit the States of North Carolina, South Carolina, Georgia, Alabama, Mississippi, for special temporary duty; upon completion of which to rejoin his station. June 22, 1907.

GLEASON, C. M., acting assistant surgeon. Granted leave of absence for twelve days from June 18, 1907. June 20, 1907.

KNOWLES, RALPH, acting assistant surgeon. Granted leave of absence for seventeen days from July 7, 1907. June 21, 1907.

RODMAN, J. C., acting assistant surgeon. Granted leave of absence for three days from June 16, 1907. June 21, 1907.

ROWLES, J. A., acting assistant surgeon. Granted leave of absence for ten days from July 15, 1907. June 19, 1907.

WALKER, R. T., acting assistant surgeon. Granted leave of absence for ten days from July 8, 1907. June 21, 1907.

WETMORE, W. O., acting assistant surgeon. Granted leave of absence for eight days, on account of sickness, from June 6, 1907. June 20, 1907.

WILSON, J. G., acting assistant surgeon. Granted leave of absence for seventeen days from July 21, 1907. June 19, 1907.

O'GORMAN, T. V., pharmacist. Relieved from duty at Memphis, Tenn., and directed to proceed to Ellis Island, New York, reporting to the Chief Medical Officer for duty and assignment to quarters. June 25, 1907.

MCBRIDE, C. R., pharmacist. Relieved from duty at Cebu, P. I., and directed to return to the States, reporting arrival at New York. June 24, 1907.

BARNETT, E. E., pharmacist. Directed to proceed to Evansville, Ind., and report to the Medical Officer in Command for duty and assignment to quarters. June 22, 1907.

SHERER, J. M., pharmacist. Directed to proceed to Memphis, Tenn., reporting to the Medical Officer in Command for duty and assignment to quarters. June 22, 1907.

APPOINTMENTS.

E. E. BARNETT and J. M. SHERER appointed pharmacists of the third class, June 21, 1907.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING JULY 6, 1907.

A. C. H. RUSSEL, surgeon. Detached from the Bureau of Medicine and Surgery, Navy Department, July 15, and granted sick leave for three months.

O. D. NORTON, surgeon. Detached from the "Missouri" and ordered to the Marine Recruiting Station, New York, N. Y., and to additional duty in attendance upon officers and men of the Navy and Marine Corps in New York City not otherwise provided with medical attendance.

O. DIEHL, surgeon. Ordered to the "Lancaster."

E. J. GROW, surgeon. Detached from the Marine Recruiting Station, New York, N. Y., and ordered to the Naval Hospital, Navy Yard, Washington, D. C.

R. SPEAR, surgeon. To the Navy Yard, League Island, Pa.

L. W. SPRATLING, surgeon. Detached from the Navy Yard, League Island, Pa., ordered to the "Missouri."

M. E. ROSE, H. A. GARRISON, J. T. MILLER, G. B. TRIBLE, O. V. HUFFMAN, assistant surgeons. Appointed assistant surgeons from June 27, 1907.

C. W. O. BUNKER, acting assistant surgeon. Appointed from June 29, 1907.

RESIGNATION.

DR. WALTER F. PARKER, Professor of Ophthalmology in the University of Michigan, has resigned. His successor has not yet been selected.

RECENT DEATHS.

DR. ALBERT W. FORD, of Brooklyn, N. Y., died from cerebral apoplexy on July 2. He was of Virginia parentage, but was born, in 1853, at Augusta, Me., where the family was temporarily located. He was graduated in arts from the University of Virginia and in medicine from the University of the City of New York, and had always practiced in Brooklyn. In 1886 he was appointed a police surgeon, a position which he retained up to the time of his death, and he was one of the most popular men connected with the Police Department. He was also for a number of years surgeon of the Sixty-ninth Regiment, New York National Guard.

DR. JOHN H. OTIS, one of the most promising young physicians of Poughkeepsie, died from cardiac disease on June 30, at the age of thirty-six years. He was the son of Dr. John C. Otis, with whom he was engaged in practice. He was especially interested in pediatrics, and at the time of his death was Commissioner of Charities of the City of Poughkeepsie.

BOOKS AND PAMPHLETS RECEIVED.

A Text-Book of Practical Therapeutics, with Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., B.Sc. Twelfth edition, enlarged, thoroughly revised and largely re-written. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1907.

Modern Medicine, Its Theory and Practice. In Original Contributions by American and Foreign Authors. Edited by William Osler, M.D., assisted by Thomas McCrae, M.D. Vol. II. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1907.

Addresses.

THE SCIENCE AND ART OF MEDICINE IN SOME OF THEIR ASPECTS.*

BY FREDERICK C. SHATTUCK, M.D., BOSTON,
Jackson Professor of Clinical Medicine, Harvard Medical School.

MEDICINE is truly a science in that it rests upon the foundation of facts ascertained or ascertainable. It is true that the fact of to-day may not be a fact to-morrow. Were this, however, sufficient warrant for denying the term science to any branch of knowledge, whose withers would be unwrung? Whatever the discovery of radium may have brought, it has not brought peace of mind to the physicists and chemists. Medical science has grown marvelously of late in spite of the complexity of the subjects involved and of the inherent difficulties which they offer to direct investigation. The more we know, the more we find we don't know. Science thus changes, and every great advance in knowledge is liable to require new hypotheses and theories, which in turn prepare the way for the next advance. The medical knowledge of the public — or laity — is always that of the profession x years ago. We are ourselves responsible for the belief that pneumonia and pleurisy are due to exposure to cold; that uric acid is the cause of dire evils, including rheumatism.

The practice of medicine is the application of known facts and principles to disease. In preventive, the higher branch of medicine, this application is close. We acquire the power effectually to prevent malaria and yellow fever only when we learn how they are carried, though this knowledge has in no way helped us in the treatment of the individual cases. The same is true of typhoid fever. In the care or cure of diphtheria, on the other hand, science has enormously strengthened our hands, and we have confident reason to hope for similar aid in other infections. The surgeon's knife is in reality a confession of failure in so far as it is used for the relief of pathological surgery. Accident surgery can be abolished only by abolishing the activity, the life of man; but there seems no reason to despair of finding out how to prevent cancers and other new growths.

Those of us who are engaged in what is ordinarily termed the practice of medicine, that is, in dealing mainly with individual cases of disease, find that there is a gap between science and the concrete case. This gap is of varying width, here and there may be easily jumped, but must usually be bridged by the art of medicine. The practitioner of medicine soon learns that disease is one thing, the person diseased another. He finds, indeed, that in very many persons demanding his services there is no disease in the sense which this word has come to convey, no definite and appreciable change in structure. Dis-ease, discomfort there is, due to impaired or disordered function, behind which may be a more or less obviously faulty mode of life, a false attitude toward life, or a mental or moral maladjustment to surroundings. The practitioner learns that human nature is essentially the same everywhere and in all times; that it does not change as does the science with which he strives to cure or alleviate the ills of men. Osler tells us that in the last analysis man has but two paramount desires: to get and to beget. The desire to get, however, is of wide extension, and as civilization advances is becoming ever wider, ranging from necessary food and protection against weather to automobiles and flying machines. But while it is true that human nature in its main features is unchanging, it is also clearly true, and vital for the practitioner to realize, that no two individuals are precisely alike in bodily and mental make-up and in environment. Each person is a kaleidoscopic figure, never exactly reproduced. Bertillon, whose name is perhaps most widely known through the application of his system of measurements to the identification of criminals, has shown that there is no duplication of size and proportion combined of that simple part of man's structure, his bony framework. Take a sufficient number of accurate measurements and you can pick your man from a multitude. Each person again has his own combination of lines on the palmar surface of his finger-tips and hands. If there is such infinite variation in the simple, is it not reasonable to suppose it to exist in the complex, in internal organs and their balance, above all in the ganglionic nervous system which should ensure the harmonious working together of the various organs and other systems? As regards the brain, indeed, there can be no question, so open to observation are its workings and so great is its capacity for education.

It is thus clear that our work is not mathematical, nor is there any danger of its becoming a penny-in-the-slot business, certainly within a future which can be of other than speculative interest to any of us here present. Science has its pure devotees — biologists, physiologists, pathologists. The art of medicine also has its pure devotees, the quacks. I assume that very few of you here present aim at the former, none at the latter. And yet there are quacks within and on the outskirts of the profession, the worst ones, for they have known light and have deliberately chosen darkness. I have known highly trained men who have gone as far professionally wrong as a man can go, bartering their birthright for a mess of pottage.

Most of you, doubtless, look forward to being practitioners. For four years now you have devoted yourselves mainly to the science of medicine, to its fundamental facts and principles, and to the methods which we employ in trying to solve the riddles of disease. Much that you have learned you will have to unlearn. How brief is the life of a textbook on the practice of medicine! Many books which well served their day and were constantly in the hands of the progressive practitioner now gather dust on the shelves of libraries. Here and there one, Watson's

*Address before the graduating class in medicine of the Medical Department of Yale University, June 24, 1907.

"Practice," for instance, has an occasional reader attracted by its style. We think we are too busy to read an old book, but when we do so, we find that the masters knew their art, though the young student of to-day knows more science. He who reads, marks, learns and inwardly digests the chapter on dyspepsia in Austin Flint's "Practice of Medicine," to take a random illustration, will be more successful in his treatment than the man who relies alone on the latest monographs on diseases of the stomach and guides his therapy overmuch by the stomach tube and chemistry.

You will now begin to apply your science, that is, combine science and art, with direct responsibility — that great teacher — all the time keeping abreast with the advance in science, entering the post-graduate school which claims you as long as life lasts.

The art of medicine is not easy to teach directly. Something of it you learn more or less unconsciously in watching your clinical teachers and their handling of cases, something negative perhaps as well as positive, something to avoid as well as to imitate. If difficult to teach there is much to learn, and it may be that thirty-odd years of practice and nearly thirty years trying to teach medical students give some warrant for offering you a few hints of possible use.

Success in the practice of medicine lies in a happy marriage between science and art. It is as sure as success in any other calling, though there are no great money prizes. He who gauges his success in life by the amount of money he makes had better resign medicine to those who seek happiness and a reasonable support in the exercise of their faculties in a calling which is ever growing, is of prime service to man and gives a chance for unlimited self-development. It means hard work, but you remember that Sir Andrew Clark defined work as the life of life.

The elements of success seem to me somewhat as follows:

1. Of course you must know your business, possess a reasonable knowledge of your profession as a science. This, with due diligence in its exercise, the law demands. The defendant in a malpractice suit is not expected to know all there is to be known on the subject. Indeed, that wise physician, Dr. James Jackson, said sixty years ago that there was at that time more known about medicine than the mind of any one man could grasp. What would he say to-day? The adjective reasonable is elastic, and must be well stretched from the legal limit to satisfy the demands of conscience and to attain real success.

2. Thoroughness. Form the habit of it from the start and deal with each case which comes to you as if it were the only case in the world. Never forget that mistakes come far more from not looking than from not knowing, from taking things for granted. Collect all your facts. For failure to do this there is no excuse. All can do it.

The evidence which leads to diagnosis and treatment is of two classes: the objective, which you gather for yourself through observation and physical examination; and the subjective, which you elicit by questioning the patient. Of the two, the former is by far the more valuable and can never be dispensed with. But we need the latter and must then often call in the aid of time before we can reach a definite conclusion. Sometimes patients get well without our really knowing what was the matter with them. Sometimes the autopsy fails to clear up the mystery. I wonder whether we are as keen observers as were our forbears who had no instruments of precision to rely on, who knew nothing of germs and their ways.

There are cases in which time is saved by making the physical examination before taking the history, though I am inclined to think this order safer for the experienced than for the younger practitioner. If there be very definite organic disease, it does not, as a rule, escape searching exploration. And yet we elders have all seen cases enough which we would pass as good risks for life insurance if we relied on the objective evidence alone. Perhaps angina pectoris affords as good an illustration as any. The heart, arteries and kidneys may seem perfectly sound, while the age of the patient and his symptoms reveal coronary change which may indeed soon prove fatal in spite of the best care, which under mismanagement is likely to prove very serious, but which so often is amenable to wise counsel persistently and faithfully followed out. The sequence and development of the symptoms, their mode of onset, may be essential to the determination of their exact pathological nature, the sudden or slow advent of paralysis, for instance. The seat of a lesion may be revealed by physical examination alone, while the nature of a lesion can only be determined by the history. Even when physical examination fully lays bare the disease, it may tell us little as to the subject of the disease, and our advice must be given to the individual, not to the average man.

In history taking there is a chance for the exercise of much art. The way in which a person tells his story in itself teaches you much about his case. The talk of some people, not always females, like the brook runs on forever, though, unlike it, gets nowhere. Others seem unable to give a direct answer to a direct question. Important facts may be forgotten, may be suppressed. Some are so foolish as to deliberately deceive, or attempt to deceive, their doctor. There are cases in which it is best to let the patient tell his story in his own way; others in which question and answer should be resorted to, either from the start or later. Just remember that people generally care little how you collect your facts. They want to help you to help them, and are ready to accept your methods, especially if tactfully applied.

It is interesting to recall that the prototype of Sherlock Holmes was Mr. Bell of Edinburgh, one of Conan Doyle's surgical teachers. The power of observation is capable of great training. Don't think thoroughness a waste of time. You will find that gradually you work quicker, though

no less surely, lower centers learning how to do that which at first only the higher could perform.

3. Common sense may for our purpose be defined as the power to arrange all the facts with an eye to perspective, with a sense of " values " which puts into the foreground those facts which are essential, properly groups those which are secondary and rejects those which are irrelevant to the case in hand. It includes the power to see what is possible and practicable in any given case. The ideal is rarely attainable and we too often have to be contented with as close an approximation as may be possible. Perhaps common sense may be made to include the power of logical reasoning. Here there may be excuse for failure such as there is not for lack of thoroughness. Clear vision and an orderly mind are not given to all in the same degree, but I am sure that they are cultivable and the problem for each of us is to make the most of himself.

4. Character, though hard to define, is very real and a very important factor in successful practice. Character is elevated by the formation of high ideals and strengthened by the resolute pursuit of them, the surmounting of obstacles internal and external. Character seems to be sometimes latent and comes out only under a squeezing process which may prove to be of incalculable benefit although painful at the time. Character will invariably reveal itself. Do not be studied or self-conscious. Do not ask yourself, " What effect am I producing? " A man should be himself, eradicating and restraining his bad, cultivating his good qualities. Do your work the very best way you know how and the result is sure to follow. The character of the physician has much to do with the obedience of the patient and with putting him into the frame of mind which leads to co-operation.

5. Enthusiasm and a genuine love for his profession, apart from its emoluments, is a quality of great value to the physician. In no other calling is there greater justification for enthusiasm. It is our privilege to try to promote the well-being of man, and we cannot do our best and highest work unless we are ever mindful of the relation of mental and moral states to ills either arising in the body or outwardly manifested by it. A love for your work will support you in discouragements of all kinds which in greater or less measure must come to all of us in life. Drudgery cannot be escaped in any calling. It is part of life, but there is no drudgery in any way comparable to that endured by the man whose sole aim is to amuse himself.

I remember hearing one of my teachers in college days, who might then with profit to all concerned have availed himself of the Carnegie Pension Fund had it existed at the time, remarking in the course of a lecture, " Gentlemen, you may think what you will, but you will find that whatever you do in life it will come down to turning the crank." God help the man of medicine, and still more his patient, who believes or gets to believing this to be true.

6. Next may come sympathy. The power of putting yourself in another's place and of realizing how he feels under given circumstances. Try to catch his point of view. If you cannot do this, act on what you think would be your own in the same situation, remembering all the time that his and yours are not necessarily the same. One personal lesson on this point is so deeply stamped on my memory that I trust you will pardon its mention. I had been seeing daily in consultation a gentleman who had special reasons for wanting to get well. He seemed on the road to recovery, and, while returning to the station with his doctor, I suggested that it might be well to skip a day, that the moral effect of so doing might be good, the fact of omitting a visit strengthening our assertion that we thought him doing well. My colleague assented. About bedtime that night I got a telegram, " Mr. A. wishes you to come down as usual to-morrow." When the doctor met me the next day he reminded me of our conversation of the previous day and of my using the words " moral effect." He then went on to state that when he told Mr. A. that no consultation would be held the next day, the patient remarked, " I think he had better come — for the moral effect! "

A uniformly kind manner, especially if it be based on kindness of heart, counts for much. Abernethy's success did not depend on his brutality. I like to recall the saying of an old French physician with whom I was visiting at the Hotel Dieu at Lyons,— " *Le Médicin guérit rarement, il améliore souvent, il console toujours.*"

Cheerfulness in the physician is a good tonic to the patient. Our fears are for ourselves and for a judicious friend or member of the family, if haply such there be. Unreasonableness on the part of a sick person is not to be regarded as it might be were he well. Illness throws some of us off our balance; but the lessons in fine courage, constancy, unselfishness, which we may all learn from our patients, are far from infrequent. The juice of character flows under the press of adversity.

Remember that the doctor's visit should be the main incident of the day to the sick man and try to make it as near the same or expected hour as you can consistently with other duties.

Once again, do not confound the sick man and his disease. Laborious days and broken nights are compensated in part by the fact that no one gets so close to the real man as the doctor. The lawyer gets closer to his money, which some may value more than themselves. The clergyman may be liable to get closer to the would-be than to the real self, to the John's John rather than to the real John, as the wholly delightful " Autocrat of the Breakfast Table " puts it. The doctor sees plenty of evil, more weakness, but still more of good in human nature. While the head must rule the heart, the latter cannot go untouched.

7. Honesty of mind is not, it seems to me, quite the same thing as common sense. Its essential feature is the power of seeing things just as they are without being blinded by either prejudice or personal interest. In the higher

degrees it is given to few. It is to be sharply differentiated from honesty of act, though when the two honesties are combined, they are precious alike to the owner and his circle, be it large or small. The man with an honest mind may act dishonestly, with wide-open eyes doing that which he knows to be wrong. His vision is clear, but his character or standard is low. On the other hand, the man of dishonest mind may act honestly and be governed by only the highest and most unselfish motives. The muddle-headed good man can do great harm and may even bring goodness into disrepute.

We can perhaps as well here as anywhere touch on the devotee of pure art in medicine — the quack, who certainly scores his successes and thus becomes worthy of analysis.

Is not the essence of quackery the claiming to possess power or knowledge which the claimant knows he does not possess? Thus dishonesty is inherent and implied. The visionary, the fanatic, the ignorant man, has deceived himself before he deceives others. He is a crank rather than a quack. But he may be both, in that he may gradually have come from clear to troubled vision, to self-deceit, a thing against which we must every one of us be constantly on our guard, so largely does the *ego* enter into our composition. The quack generally knows his human nature and the salient fact in medicine that the tendency of most pathological processes is toward recovery. He is a past master in the use of suggestion, through which the mind influences the body, the vital element in much drug action and in all forms of irregular healing. He does not hesitate to promise results which we, handicapped by a knowledge of our ignorance and by conscience, often cannot do. We are expected to cure to a degree that he is not. It therefore often happens that it is our failures, his successsses, which are spread abroad. Those who have resorted to him and have failed to get the promised relief are generally ashamed of their foolishness and keep quiet. Our failures, mistakes, or supposed mistakes, on the other hand, become the common property of the sewing circle, and may travel far by the most up-to-date means of communication. The way of the fashionable practitioner, whether he transgress or not, is not always easy.

The doctor is judged by a more or less incompetent tribunal, the proportion of people who know what constitutes evidence in a question of physical science being small. There are not as many " born doctors " as there used to be, and the seventh son of the seventh son makes less noise in the land, though his trumpet is still audible. Let us not be distressed by seeing the quack flourish near us, even if it be as the green bay tree. He, like the dog, has his day, usually a relatively short one. Neither should we let our minds be troubled by criticism, however undeserved, provided that we have the approval of our own consciences. Let us never forget that we receive far more credit which we do not deserve than we do discredit. Let us take the lean with the fat without grimace. We can recall the saying attributed to Mr. Lincoln about fooling all the people all the time. I say attributed, because an earnest searcher told me the other day that he had been unable to find the saying anywhere in Mr. Lincoln's writings or to find out when and where it was said.

With the above qualities kept constantly under cultivation, good health and good habits, you are bound to succeed sooner or later, more or less rapidly. Your lives of useful service will be happy and the ranks of those who beg their bread have very few recruits from the children of the righteous professional man.

The essential aims of undergraduate medical teaching seem to me only three: first, to teach the fundamental facts, the doing which must open before you more or less clearly the lines of future progress; second, the methods to be employed in the study and recognition of disease; third, thoroughness in work. Between the latter and the Yale spirit there is, I have reason to believe, a peculiarly close sympathy. Thoroughness is a close link between the science and the art of medicine, which latter may be summed up in the observance of the Golden Rule. Thoroughness, too, is a prophylactic against routine, the favorite child of sloth. Rules are made to break. They are our servants and should never be allowed to become our masters. We make rules to save thought, the hardest work there is. We must think whether and how far the rule applies to the given case, and let us not hesitate to break it for cause.

There are other points I would fain touch on, but I will be merciful.

A sermon, from which these remarks are not wholly devoid of resemblance, never used to be complete without a lastly and a finally. Under lastly a few words on a point of ethics as applied to the practice of medicine: Are we ever justified in deceiving or lying to our patient? My answer to that question is an unhesitating " yes," *but* — that little though significant word forces itself forward — only under conditions. Before stating my view of them let me ask anew the question of Pilate, " What is truth? " In matters medical we are dealing with x, y and z, and we must never forget that our opinion does not necessarily represent the truth. The truth as we see it may not be the truth itself. In telling the truth as the truth, we should be very sure that it is the truth, especially if in so doing we condemn the patient to an incurable and painful malady. There is generally a near friend or relative to whom we can speak frankly if we like, expressing our fears, from which we should not be too ready to take counsel. But, apart from our liability to error, it seems to me that every practitioner now and then meets a case in which neither silence nor skillful evasion avail, and in which telling the truth is sheer cruelty. The cases are not common in which a categorical lie is justified or necessary, but there are cases in which the question, " Have I a cancer? " should, in my opinion, be answered by a firm " No." There are, again, cases where the knowledge of a lues would break up a family and

wreck the happiness of the innocent without doing them any good. There would be no difficulty in multiplying illustrations. Doubtless, ordinarily, the truth, which may be stated with brutal frankness or with delicate consideration, is best for all concerned, especially if it be served with the saving grace of " as I see it," or its equivalent.

Now for the condition or touchstone. Before swerving from or denying the truth we should ask ourselves the searching question, " For whose advantage is this denial? " If it is in any measure for our advantage, or seeming advantage, let us shame the devil. Only when in our deliberate judgment the interest of the patient and his family, and that alone, is thereby furthered is the truth to be denied.

Finally, allow me, my younger brothers in the profession, to wish you God-speed and the attainment of your hearts' desire.

MEDICAL TEACHING AT HARVARD AND THE OPPORTUNITY IT OFFERS THE YOUNG GRADUATE FOR MEDICAL TRAINING.*

BY HENRY A. CHRISTIAN, M.D.,
Assistant Professor of the Theory and Practice of Physic, Harvard University, and Physician-in-Chief, Carney Hospital, Boston.

Mr. Chairman and members of the Alumni Association of the Harvard Medical School: It was with particular pleasure that I received your invitation to talk to you to-day of the teaching of medicine in Harvard and the opportunity for training it affords the recent graduate in medicine. Not being a graduate of the Harvard Medical School myself, perhaps I can discuss the teaching of medicine in Harvard from a slightly different view point from that of the man trained here. At least, the perspective of the man born and trained in Virginia and Maryland is apt to be different from that of the New Englander when each turns his gaze on the same things, and so I will not be supposed to see things just as you do. However, when we differ, I trust it will be on the friendly basis of mutual interest in the Medical School and that a consideration of these differences will emphasize what is best for that common interest.

Seven years ago I came to Boston with very different ideas of the Harvard Medical School from those I now hold. I expected to find the settled method which had grown hoary with years and the complacency of long precedent. Instead I found the restlessness of experiment in teaching methods. Six years ago the degree requirement for admission was inaugurated, and in the autumn of 1905 the fourth-year elective system was begun. These two changes alone are sufficient evidence of a desire to improve conditions, but in addition many minor changes have been made, so that the teaching in the school must have changed much since the days when most of you were students.

With the establishment of the fourth-year electives, a number of changes were made in both departments of medicine and it is of these that I desire in the first place to tell you. Through the courtesy of the trustees and superintendent of the Massachusetts General Hospital the Department of Theory and Practice has been able to offer to 28 members of each fourth-year class an elective, in which four men spend their entire time in the wards and laboratory of that hospital in intimate contact with the patients and machinery of a great hospital and under the constant supervision of one man whose hospital obligations are *nil* and whose teaching function is paramount. There each man sees the daily progress of disease in some forty patients. Each student obtains the history of assigned cases, makes physical examinations and watches the patients from day to day. Work in the wards is supplemented by laboratory investigation, such as is possible in a well-equipped clinical laboratory. All student observations are subjected to the control of instructor and house records. The ward visit of the visiting physician is followed by all four students and instructor, and in this way all patients on one service are observed. All postmortems are attended and in many instances have been done by the students themselves. The case seen on the medical side, if transferred to the surgical, is followed by the student in charge and, as a rule, all see the operation. Autopsy and operation serve to confirm or disprove for them diagnosis in a way far more instructive to the given student than is possible in any other way. It is the continued contact of student with patient that has been the most valuable feature of this course, and one of hardly less importance has been a sufficiency of time for careful observation and record, such as is impossible in the outpatient department. This elective will be supplemented next term by an additional month, increasing the number of Theory and Practice students at the Massachusetts General Hospital to 32, and the department will offer a second elective of similar character at the Carney Hospital to 16 men; four men every forenoon during two months.

A third elective was offered last year by Theory and Practice and will be continued this year, in which an opportunity is given a limited number of senior students during the first half year of carrying on clinical laboratory investigation. Last year two creditable pieces of work were published from this course.

The Department of Clinical Medicine conducts its work in a different way. It does not limit the number electing the course. The students are distributed in the out-patient medical clinics of the Massachusetts General and Boston City hospitals during the forenoon as regular student assistants to aid in running the clinics. There they see and treat ambulatory cases. Last year this work was greatly enhanced in value by the presence at each hospital of an assistant in clinical medicine, whose only duty was to supervise the students in their work. The regular management of the clinic devolved on the visiting phy-

*An address at the annual meeting of the Harvard Medical School Alumni Association, held in Boston June 25, 1907.

sician on duty, assisted by the students, and the teaching was directed independently of the management of the clinic. The experience of the previous year had shown that it was not possible for one man satisfactorily both to teach and to run the out-patient clinic.

The afternoon is spent by these men in part in ward work at the Massachusetts General Hospital, under the direction of an instructor, and in part in preparing a thesis or attending certain laboratory demonstrations. A ward visit with Dr. Shattuck is included in the week's program. One of the best afternoon exercises comes on Fridays, at 4.15, when the histories of cases which have been autopsied during the week are read and discussed. After this the post-mortem findings are reported and specimens demonstrated. Lastly, any discrepancies in diagnosis are discussed and post-mortem findings harmonized as far as possible with ante-mortem observations.

Finally, last year a new feature was introduced in the medical department, a clinical laboratory course given under the supervision of the department of Theory and Practice, which replaces portions of instruction formerly given by several departments. This course occupies two hours a day of the second half of the second year, and includes systematic instruction and practice in various clinical laboratory procedures.

This hasty review of the present teaching of medicine at Harvard brings out two things, namely, that now several men are devoting almost the entire day to teaching and that satisfactory teaching is incompatible with a satisfactory handling of an out-patient clinic by the same individual. This is a marked contrast to the former system, under which no man doing clinical teaching in medicine gave more than an hour or so to teaching work and that in connection with the management of a clinic. With the change has come a new employment for the younger men, clinical medical teaching. Clinical medical teaching as a vocation is new to Harvard, perhaps not yet fully realized. Still it bids fair to become soon a reality. What, then, has it to offer to the young medical man? First, it affords moderate income. This has been rendered possible in good part by the activity of this Alumni Association, which has raised a fund to be used annually in increasing salaries for such work and which fund you increase this year to $1,500 — the equivalent of a $37,500-endowment.

However, salary is a lesser attraction. The chief one is that such work brings to the teacher many of the clinical advantages of large hospitals without the responsibility of the routine, it brings contact with students of active mind, it compels study and familiarity with medical progress and it affords some opportunity and incentive for investigation. In short, it affords a valuable training in medicine. A number of these opportunities under the old system in Boston came to the men only after a number of years had elapsed since graduation and at a time when the activity of youth was passing into the settled calm of middle life; in other words, too late for them to give their maximal value in training.

Unfortunately, the hospital system in vogue in Boston, with its unstimulating system of promotion by seniority, makes impossible the greatest incentive for a young man's adoption of such a teaching position, — the incentive of the feeling that success in medical teaching and investigation will bring the coveted beds in a hospital and a higher place on the faculty. Success in his endeavors may bring them, but this is largely a matter of circumstance. Knowing what I do of the inner mechanism of Boston hospitals, I feel as yet unable to advise the young graduate seeking advice to follow the course, which I regard as certain to give him at the end of four or five years the broadest training and best grasp of medicine, and to assure him that attainment of these qualities will give him a hospital position. Rather am I forced to say, " Do certain routine which will train you a little, but bring a reward for faithfulness in an out-patient department, from which you will rise to the dignity of wards in due season — a long season, perhaps — even though you may learn but little more than you now know, and devote what time is left to your medical teaching and investigation. The latter will add breadth and force to your training, though it may not hasten your promotion." Gentlemen, we cannot expect to get the best men in teaching and research until the principle is established that he who does creditable work will be appointed to the out-patient department and promotion to the wards will come to that man young or old, who has best utilized his opportunities for work, whatever his seniority rank. This stimulus is needed by almost every man, and with it more hard work will be done.

Changes that must come soon in the staffs of Boston's large hospitals will give an opportunity for the hospitals to show whether adherence to the precedent of seniority promotion will continue or not. If seniority determines these promotions, I can but feel that medical progress in Boston has received a serious setback. So long as the medical school controls no hospital appointment in Boston, as is now the case, it should strive in every way possible for the principle of promotion to the best man, in order that for its teaching it may command the best local talent. Cessation of seniority promotion in Boston hospitals would, I believe, greatly aid in getting the best local men for our teaching.

I have not speculated as to the future development of the Harvard Medical School. Each can build for himself medical air castles. To maintain its relative position Harvard Medical School, however, must be active. Laboratory buildings we have in every way adequate. The crowning glory of a medical school — the hospital — we lack. I cannot refrain from saying that the Brigham Hospital will not be that crowning glory unless the appointments be controlled by the medical school, teaching be freely permitted and there be a single head to each service. A large number of patients across the street are no asset to the

student, unless he can come in contact with them and have competent instructors. Too often do we boast of the many hospital patients in Boston as a valuable asset to the medical school, forgetting how few of these are really accessible to our students. Not more patients, but more contact with patients is the present great need of our students.

If the Brigham Hospital is manned as the present Boston hospitals and be free of university control, to my mind its nearness will be its only advantage, and it may well serve as a perpetual preventive of what we need, — a university hospital. An improvised dwelling house with few patients would be better for us than a magnificent hospital, uncontrolled by the medical school, for in the former, at least, the medical school can determine the policy and appoint the best man capable of doing medical investigation and teaching, and in this wise lay the beginnings of a university hospital, which in due season will grow to be an institution that is a fit companion of our present laboratory buildings. But I have digressed from my main topic.

Notwithstanding the fact that at present the medical school cannot appoint to hospital positions the men regarded as most capable of teaching and investigation, yet the advantages of the training offered the young medical man by such an employment of his time as is afforded by teaching in the departments of medicine, are great, and these positions, I wish to emphasize, are for the young men and should be held for only a few years. Continuance in them is desirable neither for the man nor for the school. The personal pleasure in such work in itself would well recompense the man during these few years and the training gained would at least be no bar to hospital promotion. So, in those years, while awaiting an appointment in the out-patient department, medical teaching offers many attractions. If followed by the brighter men, at least, we will have soon in America a class of men from which to draw clinical professors, when freer interchange between our schools becomes possible, and who in the meantime can redeem us from the just criticism that in America rarely does a man continue clinical investigation beyond the first decade of his medical life, and that our medical leaders represent but little that was not embodied in our medical leaders of half a century ago.

For these reasons and others, I trust that the recent changes made in the teaching of medicine at Harvard will result in attracting the younger men to the positions which give them teaching experience and opportunity for clinical investigation. All effort possible on your part directed to this end will be a great boon to the medical school and a factor in the uplift of the standard of American medicine.

The Croonian lectures of the Royal College of Physicians, London, have been delivered by Dr. W. J. R. Simpson on "The Plague." — *Science.*

THE MEDICAL AND SURGICAL ASPECTS OF PERFORATING TYPHOID ULCERS.*

BY RICHARD H. HARTE, M.D., PHILADELPHIA.

Since typhoid fever has become such a widespread disease, with its apparently unavoidable and fatal complication, namely, perforation, which has been estimated to amount to as many as 16,000 annually in the United States alone, it renders a discussion of the subject one of perennial interest, and, I think I may add, of considerable value. It is only by a discussion of the relative value of the various symptoms and modes of treatment at present known to us, that we can hope to save more of these cases from a fatal termination.

Although it may be somewhat of a presumption to call your attention to a subject which has already received such able treatment by many of the physicians and surgeons of Boston, yet I venture to present for your consideration some of the conclusions that I have myself reached, with the hope of carrying home with me, as the result of your kindly discussion and criticism, some ideas which will be of practical utility to my future patients.

I cannot but feel the importance, in the treatment of desperate cases of typhoid fever, of the surgeon and physician daily seeing the patient together, as it is impossible for a surgeon suddenly called in consultation, knowing nothing of the individual peculiarities of the patient, to positively diagnose perforation. Neither does it seem necessary that the surgeon should be called in consultation in every case, particularly before the physician feels that there is cause for alarm.

The physician is of the greatest help to the surgeon in deciding on the propriety of surgical intervention. An over-enthusiastic surgeon would many a time open a patient's abdomen were not the physician at hand to remind him that sudden pains in the course of typhoid fever are not unusual; that a leucocytosis of from 10,000 to 12,000 has occurred and the patient seemed none the worse; that the patient has vomited at times without appreciable cause; or, that in another instance, abdominal pain and fall of temperature was significant of intestinal hemorrhage and not of perforation. Of course, the surgeon must in the end assume the responsibility; he cannot and he should not regard himself merely as a machine in the hands of the physician. Therefore, to render himself competent to appreciate the changes produced in typhoid fever by perforation, he must familiarize himself with the normal aspects of the disease; he should be acquainted with the slow pulse, the disproportionate high fever; the distention of the abdomen, its normal resistance and susceptibility to pain; and he should pay particular attention to the facial expression of the patient. This facial expression and the change

* Read at the meeting of the Surgical Section, Suffolk District Medical Society, in conjunction with Boston Medical Library, March 13, 1907.

which occurs in it after perforation is so characteristic, though difficult of description, that to one who is familiar with the patient's daily aspect, it becomes a surprising help in diagnosis. Hence, I think it well for every surgeon in hospital practice to keep himself fairly familiar with all the very ill typhoid patients in the wards. I have endeavored to carry out this plan with my colleagues as far as possible at the Pennsylvania Hospital, with the most gratifying results.

In the paper under consideration I wish to express as far as possible the results of our experience as obtained from the study of 80 cases of perforation, which have been operated upon by my colleagues and myself since 1901 at the Pennsylvania Hospital. I find that our experiences and the results obtained from them have already been presented in a paper by Dr. Ashhurst and myself (published in the Transactions of the American Surgical Association), based on 362 operative cases.

I wish here to express my appreciation of the very careful and accurate work which my colleague, Dr. J. A. Scott,[1] has done at the Pennsylvania Hospital. His reports have proved of great value, and for the statistics herein set forth I have largely depended on his figures. I find that Dr. Scott's studies corroborate the deductions which I have already arrived at in my previous papers on this subject[2].

From January, 1903, to March 2, 1907, there have occurred in Philadelphia 34,725 cases of typhoid fever with 3,805 deaths. Considering that at least one third of these deaths are due to perforation, we have had 1,268 perforations to deal with in Philadelphia. Some of these cases should have recovered, and it remains for the attending physicians to determine how many are to be recognized and submitted early to surgical interference, with the hope that a fair percentage of recoveries may take place. The statistics thus far compiled give too low a mortality rate, I believe, as many fatal operative cases have never been reported.

There is no doubt that certain typhoid epidemics are more virulent than others, and the resulting ulcerations occurring in the bowel are deeper and greater in number, and where perforation has occurred and the patient has been operated upon in these serious cases, secondary perforation frequently occurs with a fatal result. In our series this has been experienced repeatedly.

In summing up our work at the Pennsylvania Hospital along this line, we have operated on 80 cases of typhoid perforation, of which 15 have recovered, giving a mortality of 81.25%.

Now permit me to take up, *seriatum*, the general subject of perforation.

Predisposing causes. — The causes of perforation are numerous; among them may be mentioned race, sex, age, stage of the disease, severity of the attack, severity of the epidemic, intestinal parasites, etc.

It would appear that the negro is less disposed to perforation than the white. Out of 25 operations of my own, only one patient was colored, making 4%; and this seems to be the experience of other operators.

Males are more liable to suffer perforation than females.

As a rule typhoid fever is a disease of early life, and consequently most perforations occur between the ages of 15 and 30 years.

From a careful analysis of a large number of cases, the third week of the disease is the most usual time for perforation. It may, however, occur at any time during the height of the disease, or even before the patient feels particularly sick, as has been noted in a number of ambulatory cases.

There is no doubt, as before mentioned, that certain epidemics of typhoid fever are more virulent in character than others, the ulceration of the Peyer's patches in such instances being deeper and more extensive than in the milder cases, causing a greater tendency to perforation.

Virulent cocci or bacilli may cause a secondary infection resulting in extensive inflammation, necrosis and, later, perforation. Anything which sets up unusual peristaltic action in a previously diseased intestine — undue involuntary contraction of the abdominal muscles, straining at stool, urination, cough, sudden spasm or struggle incident to a cold bath, may be a factor in producing perforation. There is no doubt that irritating foods brought to patients by their friends should be classed as exciting causes. When perforation occurs during sleep, without any apparent exciting cause, it may rightfully be attributed to excessive necrosis.

Intestinal parasites have been mentioned as possible factors in perforation, but I do not consider them as such. I do believe, however, that they are a predisposing cause in appendicitis.

The *pathological lesion* in typhoid fever is confined largely to the last three feet of the ileum, although extensive involvement of the colon may be found, even down to the sigmoid. But it is in the last two feet of the ilium that perforations are most apt to be found, varying in number from one to six or more, and depending as to their size largely on the character and depth of the ulcers. Not infrequently at the time of the operation, when the intestine is exposed, one perforation may be found, while half a dozen ulcers can readily be detected through the peritoneum, both by the eye and by the sense of touch. These ulcers are favorable sites for future perforation. When the peritoneal coat does finally give way, the opening at first is very minute, even smaller than a pin head. It will usually be covered with a small mass of frothy mucus or liquid fecal matter. Around this area will also be found considerable masses of lymph, and in seeking for the point of perforation this lymph must be gently removed with gauze, after which the perforation will not infrequently be brought to light. Again, a large opening may exist, varying in size from the end of a pencil to the tip of the finger and permitting feces to escape. What will be noticed on the

[1] Univ. of Penn. Med. Bull., May and June, 1905. New York Med. Jour., Feb. 9, 1907.
[2] Ann. of Surg., Jan., 1904. Jour. Am. Med. Asso., Oct. 28, 1905.

operating table differs but little from what all have frequently seen in the laboratory. If cultures are made the typhoid bacillus will be found to be the infecting cause, with a low grade of peritonitis. If streptococci rather than staphylococci abound, the lymph is more abundant and the prognosis consequently more grave.

Time will not permit of a lengthy discussion of the many interesting points of this subject from a pathological standpoint, but the chief interest in doubtful cases is whether or not a perforation has taken place.

With our present knowledge of typhoid perforation there would appear to be little difficulty in making a positive *diagnosis*, but unfortunately typical cases are the exception. Not infrequently a case may present all the clinical evidences of perforation, submit to operation, and no signs of any peritoneal irritation be found. On the other hand, patients may die without any abdominal symptoms of importance and at autopsy a perforation may be found. Nevertheless, there are certain classical symptoms which must be borne in mind and which must be thoroughly analzyed in every suspected case, for otherwise errors will be made in diagnosis.

Pain is one of the most valuable symptoms in diagnosis, and the greatest attention should be paid to it. It varies in degree and in location and also in character, but it usually is more or less paroxysmal. Its severity may be so marked that the almost comatose patient may cry out with it, or, on the other hand, it may be very mild. It is usually of a stabbing character, situated most frequently in the lower right quadrant of the abdomen. It may be felt in the epigastrium and umbilical region, or in the bladder, and, in the male, at the end of the penis, or sometimes in the left iliac fossa. These facts should not be overlooked in patients who are apathetic, or are so far advanced in the toxemia of the disease that they do not appreciate pain. Thus it often happens that the first evidence of perforation is a distended abdomen with a movable dullness in the flank. I recall a case where the first sign of perforation was a violent attack of pain, causing the patient to scream out and draw up his legs in bed. This lasted but a short time, leaving only muscular rigidity upon which to base a diagnosis. On the other hand, it must be borne in mind that pain is a common thing during typhoid fever, due to the ingestion of improper food, flatulence, or a dozen different causes of irritation within the lumen of the gut. Therefore, it is imperative that this symptom be thoroughly guarded and carefully analyzed. In our experience at the Pennsylvania Hospital pain was a constant and reliable symptom in about 75% of the cases operated upon. The subject of pain is so important that I hastily run over a list of conditions which may be responsible for it. Among these may be mentioned hysteria, pleurisy, pneumonia, distended bladder, menstruation, appendicitis, peritonitis, cholecystitis, rupture of the gall bladder, liver abscess, phlebitis and thrombosis of the iliac vessels.

Manges[3] very aptly puts it when he says that the solution of some of the problems of the real significance of pain will be found when we know more about the exact relation of non-perforative peritonitis in typhoid fever.

There can be no question but that pain when present is a most valuable and important symptom and it would seem that it must always be present to more or less an extent after a perforation has taken place. But here the personal equation has always to be considered. What one patient will consider pain, another may express as only slight discomfort.

Sweating, either alone or accompanied by a fall of temperature, frequently accompanies the pain of perforation. The sweating may be profuse, involving the entire body, or only the head and neck. With it there is often a fall of temperature, and, in my experience, it is fairly consistent, varying from 2° to 4°. Where no fall of temperature occurs it may be due to the fact that the temperature had not been taken until the advent of peritonitis, which had restored it to the original range of fever. I consider it a good rule to have the temperature taken immediately and repeatedly after the occurrence of any abdominal pain, until all doubt is passed. A fall of temperature frequently accompanies intestinal hemorrhage during typhoid fever, but the hemorrhage is, as a rule, painless and usually evident in the stools in the course of an hour or so.

In considering the *temperature* it must be borne in mind that a sudden chill is a warning that must not be overlooked. In the last case I operated upon, a chill occurred some hours before a diagnosis of perforation was made. It does not often occur, but when present is significant of some sudden peritoneal irritation.

Rigidity of the abdominal muscles is one of the most valuable signs in the diagnosis of intestinal perforation, and I think its value is more generally appreciated by the surgeon than by the physician. This rigidity is *reflex* and hence is *involuntary*, depending for its production on the overflow of stimulus received in the lumbar cord from the inflamed peritoneum and is most noticeable in the right rectus and oblique muscles of the abdomen. Voluntary rigidity of the abdominal muscles is not uncommon in typhoid fever, as the patient tries in this way to protect his sore and swollen intestine from the useless pressure to which he is subjected at the hands of some physicians. I hope I may be pardoned if I say that I do not think all physicians realize what a surgeon means by abdominal rigidity. It is not elicited by trying to palpate the lumbar spine, but can be detected by the merest touch of the finger tips. The finger tips, however, must be as well trained in their work as is the skilled ear of the physician who frequently studies obscure heart lesions. It must be remembered that the sensorium in typhoid is so blunted that this symptom may not be so quickly recognized as in appendicitis.

Tenderness is not as valuable a sign as rigidity,

[3] Mt. Sinai Hospital Report, 1905.

since tenderness may exist where no perforation has occurred. It can be elicited to a more or less extent in almost every case of typhoid fever. However, when there is a definite spot of tenderness and it is accompanied by other significant symptoms, it must not be disregarded. In examining the abdomen for tenderness the rectum should never be overlooked, as a knuckle of the ileum may perforate and slip into the pelvis and thus for a time escape detection in a superficial examination of the abdomen. This was very noticeable in a case operated upon a short time ago by Dr. Stewart at the Pennsylvania Hospital. The case was suspicious, but nothing was positive until a rectal examination was made which revealed a spot of great tenderness, and when the abdomen was opened a perforated knuckle of gut covered with lymph was found lying alongside of the rectum and surrounded by exudate. The perforation was closed, the pelvis washed out and the patient recovered.

Vomiting is of so common occurrence in typhoid fever, without any apparent cause, that it cannot alone be considered as indicative of perforation, but when it occurs for the first time, and especially where it either precedes or follows pain, it should not be disregarded.

About the time of perforation a peculiar change takes place in the *facial expression*, which is most significant. It is difficult to describe, but once seen is never forgotten, being distinctly characteristic of the shock of perforation.

There is in the majority of cases an increase in the *pulse rate*. In typhoid fever the usual pulse rate is from 80 to 100 beats per minute, but after perforation it is apt to rise rapidly from 120 to 140 within ten or fifteen minutes following the onset of pain.

Distention of the abdomen is often present throughout the disease, and is not an important sign, although it becomes more pronounced after perforation. The important point to determine is whether the gas is within the bowel or free in the peritoneal cavity.

Dullness on percussion is a very fallacious sign, and palpation of the liver dullness, on which so much dependence was formerly placed, is even more elusive. Intestinal distention frequently precludes palpation of the hepatic dullness; even when air is free within the peritoneal cavity liver dullness may exist. Dullness in the flank is not always pathognomonic of fecal extravasation, as a freely movable colon with liquid feces within it may give rise to a similar condition.

It has been asserted by Crile and others that the blood *pressure* rises about the time of perforation and can be demonstrated by the use of the sphygmograph. I have not had any experience along these lines and am inclined to regard it as being of more interest to the laboratory observer than to the practical surgeon and physician.

The *examination of the blood* is now generally conceded to be of little value, or at least such has been our experience at the Pennsylvania Hospital. During typhoid fever the number of leucocytes is physiologically diminished and it would seem as though the patient's exhausted condition prevented a leucocytosis. A high leucocytosis may render positive the diagnosis of perforation, whereas a low count should be interpreted as showing that a perforation does not exist, since the patient in the latter case may be entirely overwhelmed by the typhoid toxins and no leucocytic action be possible. Kast and Gutig have shown that in typhoid fever complicated by secondary infections the leucocytes are much lower than when such infections occur alone. In the observations made by Longcope, at the Pennsylvania Hospital, on the bone marrow in cases of typhoid fever, it is shown that when the disease is complicated by a severe secondary infection, there appears to be an actual inhibition of the formation of the polymorphonuclear leucocytes in the bone marrow. A wave of leucocytosis is here described as reaching its maximum just after perforation and then subsiding.

I am firmly of the opinion that a careful blood picture should be drawn wherever possible, but that the results should never be considered, except where they confirm existing clinical signs.

From what has thus far been considered, it would appear that in a typical case of typhoid perforation but little difficulty would be experienced in making an accurate diagnosis. But this point should never be lost sight of, — that it is one thing to operate on a case of typhoid perforation, and a decidedly different thing to operate on a case of septic peritonitis, the result of typhoid perforation, which has existed for some time and which has been evinced by milder and more localized symptoms which have not been recognized and properly interpreted. Any person who has seen many cases of perforation will be struck with the difficulty of estimating the exact time of the accident. This is emphasized in the elaborate and comprehensive report by Drs. Shattuck, Warren and Cobb, published in 1900.

It has been asserted that difficulty is experienced in making a diagnosis where the question of *hemorrhage* is concerned, as to whether the hemorrhage was responsible for many of the symptoms that present themselves or not. As before mentioned, the collapse is likely to be the same in either case, yet hemorrhage is usually unaccompanied by pain or rigidity. The escape of blood from the bowel soon tells its own tale. As a rule perforation cases are seldom accompanied by hemorrhage, probably not more than 10%. In one of my own cases both hemorrhage and perforation existed, as was proven by laparotomy. The bleeding point was ligated and the perforation in the bowel closed, after the establishment of an artificial anus. In appendicitis also it may be impossible to make a positive diagnosis, especially if the appendix is perforated. In non-perforated cases of appendicitis the pain is not so severe, the temperature does not show such a sudden drop and the facial expression is not so characteristic. Peritonitis, due to pelvic or ovarian disease, can usually be eliminated after a careful vaginal examination. Gall-bladder

affections are not uncommon during an attack of typhoid, owing to typhoid bacilli finding their way into the gall bladder, causing much disturbance and even rupture. This occurred in a case a short time ago at the Episcopal Hospital. Pain in the gall-bladder region, possibly jaundice, symptoms of shock, with rigidity, dullness and possibly a palpable mass, all aid in determining the character of the invasion. The perforation of gastric and duodenal ulcers during typhoid fever simulates very much the symptoms of an intestinal perforation in the ileum, and the local signs are our chief aid in making the diagnosis. Iliac thrombophlebitis, suppurating mesenteric glands, splenic infarcts, all may cause peritonitis during the course of typhoid, and are not so characteristic of perforation. Where pain exists the greatest care must be exercised in determining its origin.

I recall two cases, one where the pain, muscular rigidity, anxious expression, etc., pointed to perforation. The regular passage of a fair amount of urine and the inability to palpate the bladder led to a tentative diagnosis of perforation. After the introduction of the catheter, however, 188 oz. of urine were evacuated, and all symptoms immediately subsided. In the other case a diaphragmatic pleurisy caused a similar train of symptoms, which subsided on a thorough fixation of the side.

The *prognosis* in typhoid fever depends largely and almost entirely upon the promptness with which the condition has been recognized and the patient operated upon, provided that the area of ulceration in the bowel is not too extensive and the patient is not too toxemic, as the result of a prolonged illness.

Of nearly 600 cases which I analyzed 24.65% left the surgeon's hands well, there being a *mortality* of 75.35%. These figures, I am convinced, are too high, owing to the tendency to report only cases in which recovery has taken place. My own experience, based on 25 operative cases, gives a percentage of recoveries of 20%. Out of 39 operative cases, up to January, 1905, reported by Dr. Scott at the Pennsylvania Hospital, there were 12 recoveries, giving a *recovery* rate of 30+%. Since January, 1905, a heavy mortality has been experienced in all operative cases at the Pennsylvania Hospital, reducing the percentage of recoveries to 18.75%.

Vaughan,[4] of Washington, reports 10 cases of typhoid perforation operated upon by him, with a recovery rate of 40%.

I cannot help but feel that as time progresses the mortality rate in these cases will be diminished, as surgeons will segregate these cases, and only operate upon those where there is a possible chance for recovery.

The *operation* and *after-treatment* of intestinal perforation is probably so familiar to every one here, that it seems hardly necessary for me to discuss its technique to any great extent. Yet I feel convinced that there are some points which may be open to question. I am convinced of the importance of operating as soon as possible after a diagnosis has been made and this should not, under ordinary circumstances, consume more than ten to twenty minutes. I never wait for the so-called reaction to take place before opening the abdomen. The valuable time that is often lost after the first suspicious symptoms manifest themselves, in making the diagnosis, in obtaining the consent of the patient or his family to operation and in the transportation of the patient from the typhoid ward to the operating room, is all too great. I look forward in all large hospitals to the time when the management will *insist* that when the patient is admitted to the medical ward the physician in charge shall have the consent of the patient and his friends to operate immediately, should the urgency of the case demand it. In cases in which there is an element of uncertainty in the diagnosis, and where the symptoms do not ameliorate, I think that an exploratory examination should be made. Experience has curiously demonstrated that where no perforation exists an exploratory examination is usually followed by improvement, and there is hardly a reported instance where operation can be said to have hastened death. In my own experience in 27 cases, two were found to be non-perforative, and they really seemed improved by their sojourn in the surgical ward and went on to a hasty convalescence.

I always employ general *anesthesia*, ether preceded by ethyl chloride (if not contra-indicated), and if this is intelligently administered the patient in a few moments drops into a peaceful sleep without a struggle. The unconsciousness thus gained on the patient's part is much more valuable in the rapid completion of the operation than are any of the advantages, imaginary at best, which can be claimed for local anesthesia. It must be remembered that ether is a heart stimulant and doubtful cases not infrequently improve so much under its administration as to render an operation justifiable.

There are few surgeons to-day who advocate anything but the right-sided incision. Those who adhere to the median incision must have had a limited experience. Seventy-three per cent of the perforations are situated within 12 inches of the cecum and 94% are in the last two feet of the small intestine. In addition to this it is very difficult, when the abdomen is opened, to determine in which direction the presenting loops of bowel run, no matter how proficient one may be with Monks' method of intestinal localization, invaluable as it is for other intestinal investigations. If the cecum is first located it is easy to trace the ileum upwards until the perforation is found. This is materially aided by having your assistant examine one side of the intestine while you are watching the other side during its rapid removal from the abdominal cavity. In this way much time is saved and there is less likelihood of the perforation being overlooked. If in searching for a perforation it is noticed that when the color of the ileum begins to fade quickly from its dark, congested shade to the normal pink,

you may be positive that you have run beyond the perforation limit, and doubtless have overlooked a small pin-point perforation, probably covered with a few flakes of lymph.

As soon as the perforation is found it should be sutured, thus preventing undue soiling of the peritoneum. In about one out of every 8 cases more than one perforation will be found. Hence diligent search should be made for all inflamed areas and every spot, even threatening perforation, should be *inverted*. The inversion of the perforation with Lambert sutures of silk is usually best done in the long axis of the bowel, as transverse sutures are more prone to tear out as the intestine resumes its normal convexity. However, under certain conditions a transverse suture may be most applicable, especially if the opening is large.

Excision of the ulcer is not only useless but harmful, as it is a waste of time and may cause hemorrhage. If the opening should be too large to preclude suturing an omental flap may be adjusted over it, or if the conditions do not readily admit of closure, an artificial anus should be established. Excision of the bowel with an end-to-end anastomosis is too severe and slow an operation, as proven by its failure in every reported case. In desperate cases, where an extensive area of the ileum is studded with large, deep ulcers, all of which are on the point of perforating and where inversion is out of the question, an artificial anus may be quickly established and the efferent loop of bowel washed out with salt solution, so as to remove all irritating substances from the surface of the ulcer, thus reducing the tendency to fresh perforation. My last case, upon which I operated about two weeks ago, was of this type.

The *toilet of the peritoneum* has been a subject much in dispute in cases of peritonitis from any cause. It depends, however, almost entirely upon the amount of soiling and extravasation that has taken place within the peritoneal cavity, as to what method shall be employed for the removal of all infectious material. If the operation has been early and little or no soiling or extravasation has taken place, all the cleansing can be accomplished by the judicious use of dry gauze.

But if, on the other hand, which is usually the case, the pelvis is partly filled with fluid, stained with fecal matter and pus, the coils of intestine smeared with escaping fecal matter, and all the area in the region of the perforation in a state of surgical filth, then I cannot see that there is any other alternative but thorough irrigation of the abdominal cavity with hot saline solution. In my opinion this is the most efficacious method of cleansing the abdominal cavity, and I am sure, if rightly done, offers the patient the best chance of recovery. I cannot see that infection is much diffused, or that the patient is much shocked by this procedure. It often occurs that the infectious material is widely diffused, but has not yet been absorbed. If adhesions have not been formed, and if the infective material can be removed quickly, absorption will be diminished, or effectually prevented. On the other hand, the time required and the traumatism frequently inflicted in the sponging process must condemn this method to the conscientious surgeon. The only other cause open is to leave fecal matter, and perhaps pus, free in the abdominal cavity, compelling the patient to take his chance to fight off the probability of infection, with no other help than that afforded by a drain.

To satisfactorily cleanse the abdomen by *irrigation* does not mean pouring a few pitcherfuls of solution into the abdomen and then mopping it out in an aimless manner. The surgeon should be provided with a large, hard rubber tube, having a lumen of ¾ of an inch, with multiple perforations, and with a rubber tube and a funnel attached to the other end. Through this funnel should be poured gallons of hot salt solution, at a temperature not less than 110° F. The tube should be inserted first down to the pelvis, then between the coils of intestine, while the surgeon separates them with his left hand while manipulating the tube with his right. During the irrigation the pulse will, as a rule, improve, partly due to the heat of the solution and the refilling of the vascular channels by absorption. To combat shock it has been suggested that adrenalin be added to the solution. I have used this, however, in only one case and with a negative result.

Drainage is best maintained by large rolls of gauze placed in those regions of the abdomen where fluid is wont to accumulate, namely, the pelvis, each loin and between the folds of intestine, along the sutured bowel. Intravenous injection of salt solution is of great aid, preventing shock and sustaining the patient during the first few hours following operation.

No little discussion has arisen as to what position patients should be placed in on their return to the ward. Some advise the extreme Fowler position, that is placing the patient in the Sims's sitting posture, in order to facilitate drainage towards the pelvis. There is no question that this is all right, in perforated gastric or duodenal ulcer, gall-bladder infections, etc., but it must be borne in mind that typhoid patients are usually exhausted by a long illness and are frequently so toxic and delirious that it is not only unwise, but almost impossible, to keep them in a sitting posture. I have seen it, to my mind, do decided harm to toxic patients, although the patient's condition after operation was fairly good. I am strongly of the opinion that the majority of cases after operation will do better in the horizontal position, and that drainage can be perfectly maintained without any undue tax on the strength of the patient.

As a rule no *food* should be given by the mouth until the third or fourth day. During this interval nourishment should be maintained by nutritive enemas, and when food is finally given, it should be of the blandest kind, for the surgeon must remember that the patient has typhoid fever as well as a sutured intestine.

Finally, I would say that I have no reason to

change the conclusions at which I arrived some time ago, and which were published in my previous paper.[5]

1. Perforation of the bowel in typhoid fever is a much more common condition than is generally supposed, being responsible for about one death in every three cases.

2. The most common time of perforation is between the fourteenth and twenty-first days of the disease and occurs in all grades of severity, from the ambulatory to the hemorrhagic type, and does not seem to be any more common in the hemorrhagic than in the milder types of the disease.

3. The ileum is the most frequent site of perforation, in the majority of instances the perforation occurring within 12 to 18 inches of the ileocecal valve. The next most frequent sites of perforation are the appendix and the cecum.

4. Pain of some kind is present in 75% of all cases. In 50% of the cases the onset is sudden and severe and of increasing intensity, localizing itself to a special zone. In 20% of the cases the pain is of slow onset, not localized, with general distribution. In some cases no pain is complained of and the usual symptoms of perforation are absent.[6]

5. Tenderness and rigidity are present to a certain extent in all cases. The latter symptom I regard as a most valuable sign, and it is rarely wanting, except in patients with unusually large and pendulous abdomens.

6. When perforation is suspected the temperature should be taken every hour, as it is only in this way that definite conclusions can be drawn with regard to any marked variation in this symptom.

7. Distention is a late symptom of perforation, usually not making its appearance until some hours after the perforation has occurred. The obliteration of the liver dullness is not regarded as a reliable sign of perforation.

8. The study of the leucocytes is of little aid, although occasionally their increase may make you more positive of the diagnosis. The differential count is of no practical value.

9. Before a positive diagnosis is made, pain caused by a pleurisy, pneumonia, cholecystitis, acute gastro-intestinal indigestion, iliac thrombosis, appendicitis, peritonitis, the passage of a renal calculus, distended urinary bladder, or even a hemorrhagic exudate into the abdominal muscles, must be carefully considered. Any of these conditions may cause symptoms similar to those caused by intestinal perforation.

10. Nature may occasionally close one or more perforations, but the only rational procedure where perforation occurs is surgical intervention. No case is too desperate for an attempt, as it has not infrequently been noted that the mild cases succumb and the more desperate ones recover.

11. In cases of doubt, where the symptoms point to perforation, the safest procedure is to operate. As a rule, cases operated on and no perforation found seem rather to be benefited than otherwise by the operation.

12. When the diagnosis has been made, I know of no condition, except possibly that of hemorrhage, where speed in operating is so important a factor in securing success, as it is in intestinal perforation. Everything should be carefully prepared beforehand and all conditions considered, so that when the operation is once begun things should move with rapidity and without any interruption.

[6] Scott.

PERFORATING TYPHOID ULCERS.*

BY FREDERICK C. SHATTUCK, M.D., BOSTON,
Jackson Professor of Clinical Medicine, Harvard Medical School.

WE are under obligations to Dr. Harte for his comprehensive and interesting paper. The closer association of work which he suggests between the physician and the surgeon would be of great value in other affections as well as in typhoid, and profitable to the patients as well as to the medical men. There are, however, practical difficulties in carrying it out. Each man has his own patients to look after, and when he has got through with those inside the hospital he usually has not too much time for those outside.

His other suggestion, that an understanding should be reached that every case of typhoid admitted to the hospital may be operated on without delay, if deemed necessary, seems to involve no serious difficulties, and should, it seems to me, be generally adopted.

It is interesting to learn that those patients operated upon without any perforation being found did so well. I find it hard to believe that their improvement was due to the operation, which was presumably done well on in the third week at about the time when the disease naturally abates. I am sure that Dr. Harte does not mean to recommend anesthesia and laparotomy as a routine remedial measure for typhoid fever.

Not knowing what Dr. Harte was going to say or exactly how he was going to treat the subject, I put down in writing what I have to say, especially from the point of view of the physician.

Perforation is the gravest complication of typhoid fever. Fortunately it is rare. Of 2,047 cases of typhoid treated in the Massachusetts General Hospital in the past ten years, it has been known to have occurred in 30, or in 1.4% of the cases. I have had no case of perforation, myself, since 1899.

It is most liable to occur in the third week, but may occur at any time after the middle of the second. It may occur in the first or second relapse, the primary attack or attacks having run a favorable course. There is no relation between the severity of the case and the liability to perforation.

The duties of the physician with regard to perforation in typhoid are four-fold: (1) He must know the symptoms suggestive of its occurrence; (2) he must be on the watch for them; (3) he must see that the nurse or attendant knows and is alive to them, in order that he be sent for at the earliest

*Read at the meeting of the Surgical Section, Suffolk District Medical Society, in conjunction with Boston Medical Library, March 13, 1907.

threatening moment; (4) he must not delay calling in a surgical colleague.

Sudden abdominal pain, accompanied or soon followed by spasm, and later by tenderness, probably, but not necessarily, localized, coming on at or after the middle of the second week, are symptoms not to be lightly regarded. Vomiting may or may not occur. Rapidly increasing leucocytosis is highly confirmatory, but we must remember that operation has proved the existence of perforation and peritonitis without increase in the white count. Here, as in other diagnostic problems, it is the association of symptoms and signs — the whole picture — which counts rather than any one symptom or sign. Rapidly increasing distention in connection with the above indications suggests that peritonitis is general.

The milder the typhoid, the more free from distention the patient; the less toxic he is, the more classic are the symptoms likely to be, other things being equal. This is fortunate, inasmuch as the hope from operation is small in a patient exhausted by a severe acute infection of usually at least two weeks' duration, with an intestine more or less paretic, with the sensorium so benumbed that it recognizes only feebly, if at all, the supervention of perforation. While perforation cannot be recognized in a certain proportion of cases, I strongly incline to the opinion that the pronounced typhoidal state is distinctly less common now than thirty-odd years ago, in my undergraduate and interne days, thanks to more rational treatment and a vast improvement in nursing.

Moreover, the fact that the early recognition of perforation may through operation save life in itself leads to greater alertness on the part of the physician than was called for in the days when opium was practically the only weapon against this form of the *vis lethalis naturae*. Nowadays, only the minority of perforations go unsuspected or unrecognized in good hospitals or under good care in private. It is surely desirable that recognition should be early and that surgical consultation be held as soon as possible. The interest of the patient is thus better safeguarded. Were medicine and surgery less closely intertwined than they are, the duty of the physician might be said to be done after recognition and calling a consultation, but many a man must, perforce, be both physician and surgeon, and, where limitation of practice is possible, there are more surgeons who practice medicine than there are physicians who practice surgery.

General considerations and the experience of the past must be given due weight in conjunction with the special features of each case before the decision is reached, whether and when to operate. I have believed that in a patient in fairly good condition and with undoubted perforation operation cannot be done too early. There seems to be some division of opinion among surgeons whether it is not wiser to wait until the first shock of the perforation has passed. There appears to be warrant for this division in the Massachusetts Hospital cases for the past ten years. I note that in the six recoveries after operation, the apparent interval between the first indication of perforation and operation was twenty-three, twenty-four, twenty- three, twelve, eight and four hours.

In 8 of the fatal operated cases, the interval was twelve hours or less. In 2 cases it was less than two hours. One of these was mine, as favorable a case for operation as one could wish for. When I made my visit in the ward, the man, who had given me no anxiety, was asleep, and, looking at his chart, I passed him by. Before I left the hospital he was reported as having severe abdominal pain. I went back to him and in about an hour he was under the knife, but died.

In the other 6 fatal cases, the interval ranged from eighteen to thirty-six or more hours. In one of these, the first symptom of perforation occurred sixty hours before operation and general peritonitis had existed twenty-four hours before, yet the patient withstood the operation and died nine days later from a secondary perforation.

It would seem to me that better results in the future are to be looked for through prompt recognition of the condition, more accurate knowledge than we seem to have at present as to the time of election, with due consideration of the special features of each case, and realization of the fact that a patient with perforation in the course of an acute, though prolonged, infection tolerates anesthesia and intervention less well than one in full health with perforation of the stomach or appendix.

MISTAKEN DIAGNOSIS IN CASES OF TYPHOID PERFORATION.*

BY C. L. SCUDDER, M.D., BOSTON,

Visiting Surgeon, Massachusetts General Hospital; Lecturer on Surgery, Harvard Medical School.

CONSIDERABLE interest and importance attaches to the knowledge of those cases of typhoid fever, in which a mistaken diagnosis of intestinal perforation has been demonstrated by operation. These instances of mistaken diagnosis fall naturally into three groups: (1) Those in which no lesion is discoverable; (2) those in which the lesion found does not involve the peritoneum; (3) those in which the lesion is found within the abdomen, involving the peritoneum.

In the first group of " no lesions found " are the following: The case of Harringham & Bowlby,[1] in which there were symptoms of typhoid perforation on the twenty-eighth day of the disease; the two cases of the collection of Shattuck, Warren and Cobb,[2] cases 22 and 23 of the first report, and the three cases recorded by Scott,[3] of Philadelphia, in a recent paper.

To the second group belong cases of pneumonia (Scott[4] records three cases), of gastritis, of enterocolitis and of hemorrhage, of Zenker's degeneration of the abdominal muscles (beginning

*Read at the meeting of the Surgical Section, Suffolk District Medical Society, in conjunction with Boston Medical Library, March 13, 1907.

with hemorrhage into the muscle), one case of a distended urinary bladder.

The symptoms of intestinal perforation, sudden abdominal pain, tenderness and rigidity, together with distention, vomiting and rapid pulse, are also symptoms of a peritonitis. Certain causes of peritonitis will be mistaken for typhoid perforation.

To the third group of cases of mistaken diagnoses belong certain of the lesions causing peritonitis, viz., *cholecystitis* and perforation of the gall bladder. Erdmann's [5] paper has noted a personal case and three cases from literature, which, added to Keen's [6] paper, makes a total of 34 cases of perforation of the gall-bladder. Seven operations were done in these 34 cases; five complete operations, with one death. All of the unoperated cases died.

Killiani [7] recently reported a case with two perforations of the gut and a perforation of the gall bladder during the fourth week of the disease. The patient lived twenty-one days after operation and died of gangrene of the lungs and empyema.

Allyn, of Philadelphia, reported in 1901 a typhoid case which died three days after operation, in the third week of the disease. No lesion was found at operation. At autopsy, however, there was discovered an opening in the gall bladder communicating with a small opening in the hepatic flexure of the colon.

Willis reports a perforated gall bladder during typhoid fever, in which two weeks after a cholecystostomy the patient died of peritonitis. A cholecystectomy might have terminated differently.

Ovarian cyst infections are recorded during the active period of typhoid fever. One case by Sudeck [8] and two cases by Lewis, Harte and LeConte [9] appear recorded. Five infections of dermoid cysts of the ovary are recorded, which were operated upon from three to eight months subsequently to the typhoid fever. Such are the cases of Werth,[10] Pitha [11] and Wallgren.[12]

Rotation and strangulation of Meckel's diverticulum is reported by Sailer and Frazier [13] to have occurred in a young adult male, during the acute course of typhoid fever — operated upon as if for a perforation of the gut.

Case XXI, Shattuck, Warren and Cobb, series 1, and the case of Körte, of Berlin, are instances of a rupture of infected mesenteric glands during the course of acute typhoid fever. In each of these cases a pure culture of the typhoid bacillus was secured from the peritoneal cavity at the time of operation.

Femoral and iliac thrombosis in three of Scott's series cause confusion in diagnosis. Thayer [14] records two such instances in Baltimore.

Of very great interest are the cases mentioned by Finney,[15] in which perforation of the intestine during the course of typhoid occurred without demonstrable typhoid bacillus, and also of interest are those cases in which a fatal *peritonitis* may develop a discoverable perforation. The Munich autopsies record 2.2% of such cases.

Gairdners'[16] Glasgow cases, five in number, are of this latter kind.

There is no doubt that an impending perforation exists in many cases — as illustrated in Case XXIV of the Shattuck, Warren, Cobb, 1st series; Case II, B. C. H. series; Scappacci, M. G. H. series, and Ayer, M. G. H., 2d series.

Murchison mentions as a cause of peritonitis during typhoid, softened splenic infarcts, abscesses in the bladder wall, abscess of the liver.

Mention is made in Scott's series of one case of a rectal ulcer and one case of pericolitis, mistaken for a typhoid perforation. Cases of appendicitis are occasionally operated upon for typhoid perforation.

I would especially call attention to a personal experience, in the following case: [17]

Adult female. Typhoid fever; end of the third week acute abdominal pain; rupture of an old pyosalpinx; rupture occasioned by an acute infection of the pyosalpinx by the typhoid bacillus. Diffuse peritonitis. Salpingectomy; the abdominal cavity irrigated and drained; the abdominal fluid contained a pure culture of the typhoid bacillus. Recovery.

A. C. S., thirty-eight years old, married. A patient of Dr. Stowe, of Medford Hillside. Massachusetts General Hospital No. 137,446.

She has always been well excepting for children's diseases.

About four weeks ago she was taken ill with malaise, cramps in the stomach and bowel and diarrhea. She went to bed May 15. She entered the hospital May 20. The abdomen was full, moderately distended, tympanitic, and the abdominal muscles were somewhat rigid. The spleen was not palpable. The temperature was 102.2° F. Pulse, 102. Respiration, 32. Hemoglobin, 80%, white blood count, 9,900. May 22 several rose spots were noted. Appearance, typhoidal. May 23, Widal reaction positive.

June 5, no distention, temperature nearly normal, very comfortable. June 8, at half past six in the morning, she had a severe abdominal pain. This pain was most intense in the lower part of the abdomen. The pain appeared just after a natural movement of the bowel. Immediately following this attack of pain the abdomen was held rather rigidly, and was moderately tender in the lower part. The pain was followed by a chill, and the temperature rose to 103.6° F. Slight shifting dullness was noted in the flanks. The rigidity of the abdominal muscles had increased. The white count rose from 9,000 to 18,000. An hour after the last chill the temperature rose to 104½°. At twelve o'clock, noon, the temperature was 105° and the pulse 130.

Vaginal examination discovered a fullness and increased resistance in the left cul-de-sac and a suggestion of bogginess. Operation at this time by a median incision below the umbilicus disclosed free, thick puriform fluid throughout the abdomen. There was no fecal odor to the fluid, nor was there any gas in the abdomen. The appendix was normal. The ileum was examined for several feet above the cecum and no perforation was found. The pelvis, where the pus was most abundant, was explored and a mass was found to the left of the uterus which proved to be a pyosalpinx, and corresponded to the tumor felt upon vaginal examination. The salpingitis was a chronic one. The wall of the sac was thick and edematous and had ruptured allowing the escape of the contents of the sac into the abdominal cavity. A salpingectomy was done leaving the left ovary. The abdominal cavity was flushed with salt solution. A gauze wick and

rubber tubes were placed in the pelvis. Excepting for a rise in temperature upon the ninth of the month, about nine days after the operation, convalescence was uninterrupted. The rise of temperature was thought at the time to be indicative of a slight relapse of the typhoid infection. The wick to the pus cavity was entirely removed upon the morning of the fourteenth, and the gradual rise in the temperature from the fourteenth to the nineteenth would suggest that retained puriform material might have been the cause of the temperature.

Pathological report: A large pus tube which had ruptured in the course of typhoid fever. The walls of the tube were covered with exudation and upon microscopical examination showed a fibrous structure with a general round-cell infiltration. Diagnosis, chronic salpingitis.— W. F. WHITNEY, M.D

The bacteriological report, by Dr. Oscar Richardson, from the Clinico-Pathological Laboratory of the hospital, is as follows: The culture showed about fifty small to medium sized, round, grayish-white, glazed colonies of a bacillus like the typhoid bacillus. Sub-cultures showed the typical growths of the bacillus of typhoid fever. Widal reaction was immediately positive with blood from a known case of typhoid fever in dilution of 1-10. The bacillus is regarded as being the bacillus of typhoid fever.

A case of pyosalpinx is referred to by Wilson, according to Fitz, and one reported by Mabit [18] (1893). In neither of these latter two cases was a bacteriological examination made. These are the only cases of pyosalpinx complicating typhoid fever I can find recorded.

Doubtless some relapses in typhoid cases are due to recent infections of the gall bladder, to impending perforations of the gut or to infections of old pus sacs and ovarian cysts.

The surgeon, before operating upon a suspected typhoid perforation, should examine the pelvis of female patients and should consider, as possibly present, the lesions thus far recorded as complicating the diagnosis.

PERFORATING TYPHOID ULCERS.*

BY FARRAR COBB, M.D., BOSTON,
Surgeon to Out-patients, Massachusetts General Hospital.

I HAVE been very much interested in Dr. Harte's complete and thorough paper, and what I have to say can add little, if anything, to what he has said and can only serve to emphasize his conclusions. I have studied, however, the cases operated upon at the Massachusetts General Hospital in the last ten years, and the analysis of these cases may be of interest to Dr. Harte and the members present.

In the early part of the year 1900 a committee from the Boston Society for Medical Improvement, consisting of Dr. George B. Shattuck, Dr. John Collins Warren and myself, made a careful study of all the cases of perforation in typhoid between the years 1895 and 1900 at the Massachusetts General Hospital, the Boston City Hospital, the Children's Hospital and St. Elizabeth's Hospital. It was my privilege to read the report of this committee at a meeting of the society.

Since I was asked to take part in the discussion of Dr. Harte's paper, I have studied all the cases of perforation in typhoid at the Massachusetts General Hospital, both those operated upon and those not operated upon, between the years 1896 and 1906. My chief purpose in doing so was to see whether the new series of cases, the majority of which occurred in the years after the report of the Improvement Society was published, would give any new information as to diagnosis and treatment, or change in any way the conclusions made in this previous report.

Of the twenty cases operated upon at the Massachusetts General Hospital between 1896 and 1906, eight cases were included in the report of the Improvement Society; the other twelve are new cases. The important conclusions of the paper read in 1900 were as follows: certain typhoids are so sick that perforation and spreading peritoneal infection cannot be diagnosed until widespread and of fatal extent. A number of typhoids may have sudden perforation with free extravasation; in these the symptoms are fulminant, but at first in some cases may be localized to a certain extent; in these cases operation must be done at once, for general peritoneal infection can become past relief in from one to five hours. In the majority of mild typhoids, beginning peritoneal infection, whether from actual perforation or necrosis of the intestinal wall, is marked by less severe warning symptoms, localized abdominal pain, tenderness, muscle spasm, with or without leucocytosis; the severe symptoms following mean general peritonitis. These warning symptoms demand serious consideration and study, but in many cases are not rightly understood or not acted upon. Complaint of abdominal pain in a typhoid should also lead to a suspicion of beginning peritoneal infection. Frequent leucocyte counts are needed in every case, and an hourly count is recommended in the presence of abdominal pain. Pain associated with localized tenderness, muscle spasm and a rising white blood count points in most cases to an operation, in all cases to a surgical consultation.

In the light of my recent study I see no reason to change the conclusions of seven years ago, with the following exception: leucocytosis, if present, may give valuable corroborative evidence, but operation should be done where there is pain and localized tenderness and muscle spasm, whether or not there is leucocytosis. The presence of leucocytosis, especially the demonstration

* Read at the meeting of the Surgical Section, Suffolk District Medical Society, in conjunction with Boston Medical Library, March 13, 1907.

of a wave of leucocytosis, is a valuable aid; the absence is of no significance. The estimation of the percentage of polynuclear cells, as advocated by Gibson, may in future be of decided value. It certainly should be obtained in all cases.

ANALYSIS OF TWENTY CASES OF TYPHOID PERFORATION TREATED BY OPERATION AT THE MASSACHUSETTS GENERAL HOSPITAL FROM 1896 TO 1906.

In addition there were three cases operated on under a mistaken diagnosis. Two of the twenty cases were operated upon by myself. Six cases recovered, 30%. This percentage of recoveries is considerably larger than in the series reported in 1900. In that series, even if one case that died of hemorrhage on the fifth day after operation were called a recovery, the percentage of recoveries would be only 19%; without this case only three cases out of twenty-one recovered, or 14.3%. In the present series, if the case that lived eleven days and died of intestinal obstruction were called a recovery from typhoid perforation, there would be seven recoveries out of twenty operations, or 35%.

Sex and age. — All the cases were males and all white persons. Thirteen cases were under thirty years of age, three cases under twelve years. Only two cases were over forty years. There were two boys nine years old and one man sixty years old. The ages of the cases that recovered are as follows: two boys nine years old, two young adults nineteen years old, a man forty and one forty-five years old. That is to say, two thirds of the cases that survived operation were boys and very young adults.

Character of the disease. — Three of the cases were very sick typhoids, and in each it is fair to state that perforation or spreading peritoneal infection could not have been diagnosed until already fatal in extent. The other seventeen cases were mild typhoids; three of them were ambulatory cases.

Time of perforation. — The only important thing in regard to these figures is to substantiate the fact that most perforations occur in the third week, but that it is not too early to expect it in the second week or too late in the fifth week. One of the cases in the medical wards that was not operated upon occurred in a relapse. In six cases perforation took place at the last of the second week or the beginning of the third; in seven cases at the middle or end of the third week; in three cases at the first of the fifth week, and in four cases during the fourth week. These figures are necessarily approximate, because of the necessity of fixing the beginning of the typhoid in many cases by the history given by the patient on entering the hospital.

Kind of onset: symptoms of perforation. — One case was a very sick delirious typhoid, in which a diagnosis of perforation could not have been made and in which operation was done for advanced general peritonitis. One case was an advanced general peritonitis brought into the accident room twenty-four hours after the first symptoms,—abdominal pain and vomiting. Eight cases had sudden free perforation with severe fulminating symptoms without warning. These cases were operated upon from two to eight hours after the complaint of pain, an average of six hours. Two of these cases recovered, one of which was a case of my own. On the other hand, in ten cases, or the majority of the mild cases, definite warning or premonitory symptoms and signs, complaint of abdominal pain, localized tenderness and muscle spasm, with or without leucocytosis, were noted from eight to sixty hours before operation was done; on an average of over twenty-eight hours before operation was done symptoms and signs were noted, which undoubtedly meant beginning peritoneal infection. In fifteen cases the surgeon, when called, found general rigidity and tenderness, with or without rising pulse and temperature and leucocytosis, and operated because of these. In five cases operation was decided on because of localized tenderness and spasm. In one of these five cases tenderness and muscle spasm were on the left, in four cases on the right side.

Leucocytosis. — In seven cases no white blood count was made. An isolated count was made in eight other cases at or just preceding operation. One case had high leucocytosis, 24,000; this case recovered. One case had 16,000 and one had 14,000. All but two of these cases were cases of advanced general peritonitis. The most advanced cases had the lowest count, 2,200 and 4,300. It was stated in the paper of 1900 that a single leucocyte count might be of little value as a diagnostic aid. I am of the opinion at the present time that a single count soon after severe symptoms have set in may or may not be of any value, and I also firmly believe that a low leucocyte count in any case should have no influence in preventing or postponing operation; that operation should be decided upon because of the abdominal pain and tenderness and the feeling of the abdominal muscles to the palpating hand. I think that in certain cases frequent and early leucocyte counts soon after the first symptoms appear may show a rising wave of leucocytosis, which will strongly bear out the diagnosis of perforation made because of other physical signs and symptoms. Three operated cases and one unoperated case illustrate this wave of leucocytosis well. In one case four hourly counts showed a rise from 6,800 to 14,000. In another case three hourly counts, from 4,200 to 10,000. In the case which was not operated upon three leucocyte counts in seven hours showed a rise from 11,000 to 26,000. In no case was the relative proportion of polynuclear cells studied.

Intestinal hemorrhage. — In two cases the records note intestinal hemorrhage for at least two or three days before operation.

Temperature and pulse. — In the majority of cases the temperature was recorded as rising. In only five cases was there a drop in temperature at the onset of severe symptoms and in only two did the temperature fall to normal or below. In all the cases the pulse increased rapidly in rate. A chill

was noted at the onset of severe symptoms in only two cases. Vomiting was recorded in eight cases.

Peritonitis. — Widespread general peritonitis was found at operation in all but seven cases. In these seven cases there was some turbid fluid and injection of the intestines localized to the neighborhood of the perforation. In thirteen cases there was no record of cultures taken. In the seven cases in which cultures were recorded the organism found was the colon bacillus. No attempt was made to isolate the bacillus typhosus by cover slip method.

Site and character of the perforation. — In nineteen cases the site of the perforation was in the ileum. In one case it was said to be high up in the jejunum. In one case the perforation was in the ileum four feet from the cecum; in most of the cases it was under twelve inches from the cecum. The size is given, varying from a pin-head to a quarter of an inch in diameter. In two cases necrotic gangrenous patches without gross perforation were the cause of the peritoneal infection. One of these cases died, the other recovered.

Anesthesia. — In one case cocaine was used, followed by ether. In three cases gas and ether were used. In sixteen cases ether alone was used.

Incision. — The cases were about equally divided between incision through the right rectus muscle and median incision.

Search for additional perforations. — Deliberate search for additional perforations was recorded as made in six cases. In only one case was a second perforation found. A second perforation was the cause of death in one of the cases, as found post-mortem. On one of the cases time was taken to invert six thin areas of intestinal wall after the actual perforation had been treated.

Method of closure of perforation. — In two cases a purse-string suture of silk was used. One of these cases recovered. In seventeen of the cases the perforation was closed with single or double rows of silk sutures. In one case which came to autopsy the question was raised whether the cause of death was not largely due to intestinal obstruction, because of excessive inversion of the intestinal wall by two rows of stitches. In one case it is interesting to note that no attempt was made to suture the perforation, but a Mixter glass tube was tied in. This was the case in which six thin areas of intestinal wall were inverted. This case resulted fatally.

Irrigation and drainage. — Only one case was sewed up tight; this case died. Drainage was used in nineteen cases. In the majority of instances cigarette drains were used, but in two or three cases rubber or glass tubes were used in addition. In four cases no irrigation was done; one of these cases recovered.

Analysis of results. — Six cases recovered, 30%. One case lived eleven days and died from intestinal obstruction, caused by fibrous adhesions. Four cases lived from three to eight days, dying eventually from general peritonitis. In one of these a second perforation was found post-mortem. Three cases died in from half an hour to ten hours, the cause of death being largely due to shock of operation. The remaining seven cases died within forty-eight hours of general peritonitis.

This study has emphasized the conclusion that in many cases the warning or earliest symptoms and signs of typhoid perforation, which mark the period when operation could be done with the greatest chance of saving life, are not recognized as sufficiently important by many physicians and surgeons. The most important thing that the discussion of this subject could bring about would be to make men realize that if operation is delayed until the signs and symptoms of severe general peritonitis are present, the result of the operation will usually be fatal, and to realize that in the majority of cases perforation or localized peritoneal infection through necrotic areas of the peritoneum is a somewhat gradual process and that there are definite typical, often localized, signs and symptoms, and when these appear operation should be done without delay; that complaint of abdominal pain by a mild typhoid almost always means a beginning infection.

THE SO-CALLED "OCHSNER MUSCLE" OF THE DUODENUM.

BY WALTER M. BOOTHBY, A.M., M.D., BOSTON,
From the Anatomical Department of the Harvard Medical School.

IN 1905, before the American Surgical Association, Ochsner called attention to what he considered an hitherto undescribed sphincter of the duodenum, situated at from 2 to 4 cm. below the entrance of the common duct. Again, in July, 1907, through the *American Journal of Medical Sciences*, he published some further observations.

A careful study of his two articles led me to believe that there was still legitimate doubt as to the existence of any such sphincter muscles as he described, and for the purpose of definitely proving or disproving its existence, I undertook the following investigation:

(1) Through the courtesy of Professor Dwight, of the Harvard Medical School, I was given opportunity to examine intestines of the subjects of the first and fourth year classes of anatomy. I examined twenty-five in all. In none could I demonstrate macroscopically the existence of any sphincter muscle; by palpation thickenings of the wall could be demonstrated, but in every instance this thickening could be accounted for by the irregularities of the mucous membrane.

(2) Six duodena were carefully removed and hardened in 60% alcohol. The serous covering was carefully dissected off. By this method it was seen that the number of the muscle fibers, both longitudinal and circular, varied slightly in places, but no increase of fibers sufficient to be deserving of especial designation as a sphincter muscle was noted. Further, in the whole study of the thickness of the muscle wall, due allowance must be made for the degree of contraction or expansion of the longitudinal fibers at different points, causing variations in thickening of circular fibers at the time of death.

(3) For the purpose of more accurate estima-

tion of the thickness of the muscle layers, I had prepared for me, by Mr. Morris, the technician in the laboratory of surgical pathology at the Harvard Medical School, a series of microscopical sections of twelve duodena obtained, through the courtesy of Dr. F. B. Mallory, from the autopsies at the Boston City Hospital. The duodena were hardened in Zenker. Each duodenum was carefully and evenly cut along the middle of the greater curvature and divided into ten blocks, from which sections were made and stained with methylene blue and eosin. This gave a cross section of the circular and longitudinal section of the longitudinal muscular fibers throughout the whole extent of the duodenum from just above the pylorus to one inch below its termination.

In these sections no general uniform increase in number of the circular muscle fibers could be demonstrated such as would constitute a permanent sphincter muscle. As will be seen by referring to detailed measurements of two of these, which I give below, there is more or less irregularity in the thickness; this irregularity is slight as compared with the average thickness of the duodenum and insignificant in comparison with the true sphincter at the pylorus. I have made a few sections lower down in the intestinal tract, which show this same fractional variation. The second duodenum detailed below is of special interest. Dr. F. B. Lund was present at the autopsy. He remarked, while operating on the patient some four weeks before, that the duodenum was markedly distended and at the time spoke of the possibility of the "Ochsner muscle" causing a constriction; as will be seen the thickness though irregular forms no sphincter muscle.

* For measurement an ocular mem. was used, therefore thickness could not be expressed in mm.

CONCLUSION.

The musculature of the duodenum (especially the circular layer) presents certain irregularities in its thickness; these irregularities are slight as compared with the average thickness of the muscle, and, compared to a true sphincter, the pylorus, are insignificant. In short, I found no grouping of circular fibers in the duodenum which could be considered an anatomical sphincter muscle, though undoubtedly there are moderate variations in the thickness.

Reports of Societies.

MAINE MEDICAL ASSOCIATION.

THE fifty-fifth annual meeting of the Maine Medical Association was held in Lewiston, June 12 and 13. The meetings of the Association have been held annually in Portland for many years, with the exception of a meeting held in Bangor, about ten years ago, but the attendance was large and the sessions well conducted. The papers read, while fewer in number than has been customary, were of rather unusual merit and interest, with discussions that were free and at times bordered on sharpness.

The morning session of the first day was called to order by the president, Dr. C. E. Williams, of Auburn.

Prayer was offered by the Rev. I. C. Fostin, of Trinity Church, Lewiston.

The treasurer, DR. A. S. GILSON, of Portland, read his report, which was referred to an auditing committee.

It was voted that the reading of the secretary's report be omitted.

DR. WALTER E. TOBIE, of Portland, was appointed official reporter.

It was voted to receive and publish in the Transactions, the reports of visitors to the Medical School of Maine, visitors to the Maine Insane Hospital and visitors to the Eastern Maine Insane Hospital.

DR. JOHN A. DONOVAN, of Lewiston, presented a paper on

INGUINAL HERNIA,

which was read by DR. JOHN STURGIS, of Auburn. Dr. Donovan emphasized the following important facts: That hernia operations to-day are not as difficult as formerly, since the patient comes to operation earlier. That high ligation of the sac is an important step and that transplanting the cord adds relatively little to the value of the Bassini operation, except in obese individuals, with large herniæ.

DR. EDWIN F. PIERCE, of Lewiston, read a paper on

VENTRAL HERNIA,

in which he reported three cases which he believed died of post-operative intestinal paresis. In these cases a vertical incision was employed upward from

the umbilicus and Dr. Pierce believes that the cutting of the terminal filaments of the anterior divisions of the thoracic nerves caused paresis of the intestines through their connection with the sympathetic supply of the intestines. He stated further: "I believe that the superiority claimed for the transverse incision and the transverse suturing of the abdominal wall as practiced by the Mayos and some other surgeons in operating for ventral herniæ above the umbilicus, is due not so much to a lessening of suture tension and intra-abdominal pressure as to a lessening of nerve interference."

DR. STEPHEN H. WEEKS, of Portland, commended Dr. Pierce for reporting unfavorable cases. He favored the longitudinal incision, cutting out the indurated edges and closing in the manner giving the least tension. He expressed his belief that when death occurs it is usually the result of surgical sepsis.

DR. JOHN STURGIS, of Auburn, felt sure that death was not due to sepsis in the cases reported by Dr. Pierce.

DR. ADDISON S. THAYER, of Portland, read the

REPORT OF THE COMMITTEE ON LAWS RELATIVE TO THE COMMITMENT OF THE INSANE

as follows:

Your Committee on Laws Relating to the Commitment of the Insane, appointed five years ago, to consider and to act upon changes recommended by your president, has reported progress from year to year, and now has the happiness to report a result.

The legislature of 1907 enacted into law the Commitment Bill, exactly as printed in the Transactions of this Association, except for the following single addition: "Nothing herein contained shall require a judge of probate to appoint a hearing for the purpose of this act in any town other than the shire town of the county or the town in which said person resides."

The bill now stands as Chapter 50 of the Public Laws of the State of Maine, passed by the seventy-third legislature. The new law enables the friends of an insane person to secure legal commitment, either through action by a municipal board, as heretofore, or through action by a judge of probate.

A full history of this statute — how it was suggested, considered, drafted, revised, introduced, debated, rejected, re-introduced, opposed, re-considered and finally adopted — would be a record of contention, unlikely to stimulate or encourage effort for the betterment of our laws. Your committee is impressed by the wisdom of a conservative hesitancy on the part of this Association in all matters which involve political activity.

Your committee requests that it be discharged.

Respectfully submitted,

ADDISON S. THAYER.
D. A. ROBINSON.
O. C. S. DAVIS.

DR. S. J. BASSFORD, of Portland, read a paper on

INFANTILE PARALYSIS WITH SPECIAL REFERENCE TO TREATMENT IN THE EARLY STAGES BY STATIC ELECTRICITY.

DR. ESTES NICHOLS, director of the Maine State Sanatorium, at Hebron, read a paper on the

DIAGNOSIS, PROGNOSIS AND CONTROL OF PULMONARY TUBERCULOSIS.

Dr. Nichols said that a large number of persons who are regarded as being generally delicate, in reality suffer from tuberculosis in a latent form, needing only some acute infectious disease to light it up. Significant symptoms of early tuberculosis are slow convalescence from acute infectious disease, ill looks, loss of weight, tachycardia, slight elevation of temperature, slight but persistent cough, streaked hemoptysis, pleurisy, asthma and other symptoms and affections.

Dr. Nichols advocated as important prophylactic measures, the care of the sputum, disinfection of rooms and houses and the detection and weeding out of tuberculous cows. He believed the great dissemination of tuberculosis to be the advanced tuberculosis patient, and urged that physicians bring to the attention of municipal anthorities the necessity of establishing hospitals for incurables and maintaining the district nursing plan.

DR. S. H. WEEKS spoke of the great need of more money to carry on the work of suppressing tuberculosis.

DR. WALTER E. TOBIE, chairman of the Portland Board of Health, told how the board had urged the need of a segregation hospital before two city governments and had finally secured a $2,000 appropriation for general tuberculosis work. A municipal tuberculosis nurse had been engaged and the work of education begun, and although every physician in Portland had been politely requested to report their cases, in three months' time but twelve had been so reported, and four of these by medical members of the Health Board. This in a city of 55,000 inhabitants and in a state where a statute exists making compulsory the reporting of these cases. Dr. Tobie spoke of the tuberculin test as enforced by the Portland Board of Health, making compulsory the testing of all cows whose milk entered Portland.

FIRST DAY, AFTERNOON SESSION.

The session was called to order at 2.15 by the president, DR. E. C. WILLIAMS.

DR. FREDERIC H. GERRISH, of Portland, assumed the chair, while the president delivered his address.

DR. WILLIAMS said in part: "The numerous hospitals springing up in all sections, notwithstanding their objectionable features, are of incalculable benefit in the general uplifting of the medical profession. Not alone is surgical skill being markedly increased, but medical and surgical diagnosis is being rapidly advanced. These hospitals are not only educating those officially connected with them; but, being easily reached, physicians and surgeons from outlying towns are bringing patients to them for diagnosis, in which they participate, and for treatment, which they observe, and whether they concur or differ, the mental stimulus is the same. . . . Each man who has an assured living practice, for his own sake and for the sake of his professional brethren, should fix his fees with regard to the value of the service rendered, rather than to attract patients by underbidding his associates. By adopting this simple rule the whole problem of compensation for professional services would be solved and all would be benefited."

Dr. Williams thought that contract practice might properly be relegated to the young physician struggling for a foothold, and for him only as a temporary expedient. He urged that the profession take a solid stand on the insurance question and favored the five-dollar fee for examination. He recommended that a committee be appointed to appear before the next legislature and endeavor to secure legislation to prevent the abuse of medical charity by hospitals.

The Association voted thanks to the president, and a committee was appointed to consider the recommendations made in his address, consisting of Drs. D. A. Robinson, of Bangor, Wm. Lewis Cousins, of Portland, and B. F. Sturgis, of Auburn.

DR. EDW. M. FULLER reported as delegate to the American Medical Association.

A nominating committee was appointed, consisting of Drs. E. G. Abbott, of Portland; Owen Smith, Portland; H. H. Cleveland, Auburn; B. L. Bryant, Bangor; Eben Marston, Bath.

DR. MIAH B. SULLIVAN, of Dover, N. H., read a paper on

ACCIDENTS AND INJURIES AND SOME OF THE MEDICO-LEGAL QUESTIONS ATTENDING THEM.

Dr. Sullivan spoke of the liability to error with special reference to nervous affections and malingering. He said in part: "We are all liable to error in the diagnosis of these symptoms of nervous conditions, but more prone to error if we espouse the cause of the plaintiff or defendant too strongly, thus insidiously leading us astray. If called upon to make a medico-legal examination, it should be made as judiciously as though it was a private individual coming to consult us; and if, after careful examination and analysis, our opinion is not one that could be brought out successfully in court, to the advantage of the plaintiff or defendant, drop from the case if the truth is not desired rather than publicly swear to a statement that can be successfully torn to pieces by another and calling down upon the medical profession the ridicule of the attorney and even of the judge." There can be no doubt that opinions may differ broadly regarding the diagnosis and prognosis in the various forms of traumatic lesion to the nervous system, so there will always be grounds for honest differences in opinion. The legal profession is inclined to consider it a huge joke to hear these radical differences of opinion between medical men, yet hardly a day passes that legal opinions are not properly reversed by the highest courts in the land.

"While it must be difficult for the medical witnesses for plaintiff and defendant to agree on every point, yet it seems to me that a joint examination followed by a fair discussion of the case would leave us in much better standing before court and jury on being summoned to the witness stand, and leave out some of the unfavorable comments on medical witnesses." "A bill has recently been introduced in the Maine Legislature, I understand by the Eminent Chief Justice Emery, of this state, that covers the questions of medical evidence in an excellent manner and if it becomes the law of the state, it will be an object lesson to the law makers of other states and will be adopted undoubtedly by them."

DR. G. H. WEEKS thought that opposing medical counsel might meet and agree and thus present a better appearance in court.

DR. GORDON said that he was surgeon for the Maine Central Railroad and saw many of these cases. The attending surgeon on an accident case should not cheat himself, but should hold a conscientious belief. He advised medical men not to let lawyers own them.

DR. JOHN STURGIS said that he had been connected with a case against the Maine Central Railroad, where he believed disease existed and that the corporation surgeon was entirely wrong. That was ten months ago and he now has the proof in an ankylosed joint. We should not let a corporation own us any more than we should let a lawyer.

DR. PHIPPS, of Gorham, N. H., agreed with Dr. Weeks that opposing medical experts should meet and confer.

DR. ADDISON S. THAYER, of Portland, felt that Chief Justice Emery's plan was a great advance over present methods and that in time something of the sort would be adopted. The idea is for a judge, after consulting both sides, to appoint a competent medical expert to determine the merits of the case. It simplifies matters, reduces expenses and prevents clouding the minds of the jury. It is better than the one and only test we now have for sanity.

DR. BIGELOW T. SANBORN said that the difficulty in Dr. Weeks's plan was that the legal counsel for or against would object to a conference of the medical counsel, and if they did so meet might dispense with their services.

DR. T. L. DICKERSON, of Houlton, said that the trouble with a conference of medical men was that the master mind was likely to prevail, and legal counsel would not take the chances of having their experts' minds swerved by that of the opposing expert.

DR. FREDERIC H. GERRISH, of Portland, said that he was not mercenary, but that he objected to serving as a medical expert for a *per diem* fee many times less than his services would command elsewhere. We should not be robbed by the state. He cited an instance where a surgeon, perhaps the best in the state, had his fee cut down by a chief justice to twenty-five dollars a day.

DR. A. J. BRADBURY, of Oldtown, read a paper on

PNEUMONIA TREATMENT IN COUNTRY PRACTICE.

On motion of Dr. Walter E. Tobie the paragraph in the By-Laws, which stated that *Transactions* should not be sent to members in arrears, was changed, so that each member receives the *Transactions* as soon as published.

DR. W. P. GIDDINGS, of Gardiner, read a paper on

BODY AND MIND WITH INCIDENTAL REFERENCE TO THE LAW OF HEREDITY.

DR. B. L. BRYANT, of Bangor, read a paper on the

RATIONAL TREATMENT OF NERVOUS DISEASES.

DR. ADDISON S. THAYER, of Portland, read a paper on

PSYCHO-THERAPY.

The three papers constituted a symposium on nervous diseases and were discussed in common.

DR. CHAS. B. WITHERLE said, as regards Psycho-therapy, that we must first exclude organic disease and study each individual case. This kind of treatment requires more time than the busy practitioner can afford to give to it. He did not believe that psycho-therapy must necessarily presuppose sanity, but that it was useful in border-line cases and curable insanity.

DR. M. M. JOHNSON, of Hartford, Conn., spoke of the value of psycho-therapy and said that it should not be allowed to drift into the hands of quacks. It must certainly fail in organic diseases.

DR. E. E. HOLT said that we should have case records kept of all scholars from the time of their entering school. Such records would be of great value to assist in our analysis of the human race.

DR. JOHN J. GEHRING, of Bethel, said that he was pleased that general recognition had come, though tardily, to the branch of therapeutics advocated in this Association fifteen years ago by Dr. F. H. Gerrish. Dr. Gehring also said that he desired to add his practical testimony to the value of hypnotism as a therapeutic agent and believed it a useful agent for the physicians' employment. Suggestion is the factor that many cults employ and should be adopted by intelligent and scientific physicians.

DR. ALFRED MITCHELL said that, while all physicians help invalids and lighten their existence by their mental influence, he had an inwrought prejudice against the occult, mysterious and unfathomable.

DR. F. H. GERRISH said that hypnotism had been criticised and by implication, at least, branded as dishonest. He believed it fully as honest as the Dubois method, scientific and worthy of adoption.

DR. ADDISON S. THAYER said that Dr. Gerrish had

shown forcibly the power of hypnotism, but that it was not available for most practitioners. He did not consider it dishonest.

DR. JOHN H. ALLEN, of Portland, read a paper on

DIAGNOSIS AND EARLY TREATMENT OF MASTOIDITIS.

Dr. Allen emphasized the following points:

1. That mastoiditis is very largely a preventable disease.

2. That in order to abort it, it must be recognized and treated at an early stage.

3. That such treatment must often be instituted, if at all, by the general practitioner.

Dr. Allen advocated early incision of the tympanic membrane and dwelt upon the importance of conserving the hearing function.

DR. D. A. ROBINSON, of Bangor, reported for the Committee on President's Address and advised that a Committee on the Abuse of Medical Charity and a Committee on Reorganization be appointed.

DR. J. W. BERDE, of Auburn, reported for the Committee on Resolutions on the Death of Dr. Alonzo Garcelon. Dr. Garcelon was a charter member of the Association and the last to pass away. He was also a charter member of the American Medical Association, and was a regular attendant at the meetings of both bodies up to the time of his death.

DRS. WALLACE K. OAKES, of Auburn, and D. A. ROBINSON, of Bangor, both read papers on

EXTRA-UTERINE PREGNANCY.

The following officers and committees were elected and appointed: President, Dr. B. B. Foster, Portland; 1st Vice-President, Dr. Alfred D. Sawyer, Ft. Fairfield; 2d Vice-President, Dr. O. C. S. Davies, Augusta; Secretary, Dr. Walter E. Tobie, 3 Deering St., Portland; Treasurer, Dr. Arthur S. Gilson, 117 State St., Portland. Censors, Drs. B. L. Bryant, Bangor; J. D. Cochrane, Saco; G. A. Pudor, Portland; W. L. Haskell, Lewiston; H. L. Bartlett, Norway. Publication Committee, Drs. Walter E. Tobie (*ex-officio*), Portland; Stanley P. Warren, Portland; John H. Allen, Portland; Edwin J. Gehring, Portland; Chas. H. Hunt, Portland. Necrologist, Dr. H. F. Twitchell, Portland. Business Committee, Drs. D. A. Robinson, Bangor; B. L. Bryant, Bangor. Entertainment Committee, Drs. E. B. Sanger, Bangor; Chas. H. Burgess, Bangor. Committee on Hospital Abuse, Drs. B. L. Bryant, Bangor; A. H. Sturtevant, Augusta; H. H. Cleveland, Auburn; H. B. Palmer, Farmington; Hiram Hunt, Greenville; B. F. Bradbury, Norway.

The Board of Censors voted that the next annual meeting be held in Bangor, June 10 and 11, 1908.

Thursday evening the annual banquet was held and the annual oration delivered by Dr. WM. T. COUNCILMAN, on the subject of

TUMORS.

Dr. Councilman's oration was illustrated by stereopticon pictures and was of intense interest.

The closing session was held in New Odd Fellows Hall, Auburn, Thursday evening, June 13, immediately following the annual banquet. Dr. D. A. Robinson, of Bangor, presented to the Association a proposed new Constitution and By-Laws to be voted on, at the next annual meeting. This is the same Constitution proposed by a Re-organization Committee in 1905 and voted down by the Association in 1906. For a number of years the American Medical Association has made efforts to have the Maine Medical Association adopt its plan of organization for state societies, and the proposed Constitution is modeled on lines approved by the national body. According to the present Constitution any change requires presentation at an annual meeting, publication in the *Tranactions* and notification to each member before the next annual meeting, at which time a two-thirds vote will secure the desired change. Maine, Massachusetts and Virginia are the three states that have not adopted the American Medical Association plan, but have preferred to cling to their present Constitutions. The attitude of those who oppose the change in the Maine Medical Association is not one of hostility to the national body and, in fact, most of those who prominently urge that the present Constitution be retained are members of the American Medical Association. The outcome of the Bangor meeting will doubtless be watched with interest.

RHODE ISLAND MEDICAL SOCIETY.

THE ninety-sixth annual meeting of the Rhode Island Medical Society was held in Providence, June 13, 1907.

The president, DR. C. F. BARKER, of Newport, presided.

The House of Delegates elected the following officers for the ensuing year: President, Dr. C. V. Chapin; First Vice-President, Dr. Frank B. Fuller; Second Vice-President, Dr. Eugene Kingman; Secretary, Dr. S. A. Welch; Treasurer, Dr. George S. Matthews. Committee on Arrangements, Drs. P. Williams, W. B. Cutts, J. B. Ferguson. Committee on Publication, Drs. G. D. Hersey, C. M. Godding, G. T. Swarts. Committee on Library, Drs. H. G. Miller, G. D. Hersey, G. W. Porter, G. L. Collins, F. L. Day. Committee on Necrology, Drs. H. C. Putnam, E. B. Harvey, L. F. C. Garvin. Committee on Legislation, Drs. G. T. Swarts, W. F. Gleason, W. L. Munro, C. V. Chapin, S. A. Welch. Curator, Dr. W. J. McCaw. Auditor, Dr. Jay Perkins.

Announcement was also made of the appointments by the president, as follows: Committee on Building, Drs. H. G. Miller, J. W. Mitchell, R. F. Noyes, F. H. Peckham, F. T. Rogers; Medical Education (member for three years), Dr. J. M. Peters; Member of national legislation committee of the American Medical Association, Dr. G. T. Swarts; member of House of Delegates of the A. M. A., Dr. John Champlin.

The commitee on contract work, through Dr. George D. Hersey, chairman, presented the following resolution, which was passed:

Resolved, That contract practice requiring a physician to attend people not in destitute circumstances, for a sum much lower than the ordinary fee, is unbusinesslike, undignified, unfair to other practitioners and derogatory to the best interests of the medical profession.

The committee has previously recommended that active measures of reform be left to the district societies.

DR. GEORGE W. PORTER, having resigned active membership, was elected an honorary member.

Announcement was made by President Barker of the deaths since the quarterly meeting in March of three members of the society: Drs. W. Frank Morrison, C. T. Gardner and Valentine Mott Francis, and of the election to membership of Dr. Edward J. Logan and Dr. Margaret S. Hardman, of Providence, and Dr. Cora G. Yates, of Pawtucket.

The trustees of the Fiske fund reported that the prize of $520 for the best essay on "Diet in Typhoid Fever" had been awarded to Dr. John Benjamin Nichols, of Washington, D. C.

For 1908 a prize of $200 is offered for the best essay on "Has Surgical Treatment Lessened the Mortality of Appendicitis?"

For 1909 a prize of $200 is offered for the best essay on "The Mode of Infection and the Duration of the Infectious Period in Scarlet Fever."

The trustees of the Chase-Wiggin fund reported that no essay worthy of a prize had been received. For 1908 a prize of $75 is offered for the best popular essay on "Tea and Coffee and Their Injurious Effect."

Dr. I. B. Woodward was introduced as delegate from the Massachusetts Medical Society. Dr. Woodward presented the greeting and good wishes of his society.

He described the very successful meeting of the Massachusetts Society just held, where the keynote of the addresses was the growth of unity among the physicians and between the societies.

Dr. Woodward said that the credit of originating the custom of sending delegates to other societies belonged to the Rhode Island Medical Society, who in 1862 sent the first delegates to Massachusetts. These delegates were Dr. Joseph Moran and Dr. Sylvestus Clapp. They were promptly welcomed and delegates appointed to Rhode Island and the custom has continued to this day.

Dr. Frank B. Sprague reported

TWO CASES OF FOREIGN BODY IN THE RIGHT PRIMARY BRONCHUS.

The first was a ten-ounce tack in a boy a little over four years of age. A radiograph showed the tack and also a dark mass below. The operation consisted of etherization, tracheotomy, the use of Dr. Kelly's cystoscope and extraction with long uterine forceps. Through the cystoscope the tack could be seen in the bronchus. After removal there was a discharge of seromucus, which had accumulated below the tack. Before the operation the temperature was 104°, the respiration very rapid and the pulse hardly to be counted.

In the second case an eighteen months' baby had a piece of peanut in the right bronchus. There was great dyspnea and an alarming condition. The same general method was followed as in the first case, using ether, the cystoscope and a uterine tenaculum with a part of the end broken off to hook up the peanut. In both cases there was a prompt recovery.

Dr. John Champlin read a paper on

THE BUSINESS SIDE OF THE PHYSICIAN.

Dr. John W. Keefe read a paper on

THE VALUE OF CYSTOSCOPY AND URETERAL CATHETERIZATION AS AIDS IN SURGERY.

The annual address was given by Dr. George C. Smith, of Boston, on

THE PSYCHIC FACTOR IN DISEASE.

Book Reviews.

The American Illustrated Medical Dictionary. By W. A. Dorland, A.M., M.D., Assistant Obstetrician to the University of Pennsylvania. Third edition, revised and enlarged. Philadelphia and London: W. B. Saunders & Co. 1905.

The third edition of this excellent dictionary is similar in form and approximately the same in size as its predecessor. Naturally, with the rapid growth of medical science and its complicated terminology, the task of a lexicographer is not an easy one. Revision must be constant and painstaking. New words must continually be incorporated and obsolete ones discarded. For example, in this edition, appearing two years after the second, several hundred new terms have been defined. Many of the tables have also been amplified and improved. We have continually made practical use of this book and, although not so encyclopedic as some others, have found it eminently satisfactory.

A Text-Book on the Practice of Gynecology for Practitioners and Students. By William Easterly Ashton, M.D., LL.D., Fellow of the American Gynecological Society; Professor of Gynecology in the Medico-Chirurgical College and Gynecologist to the Medico-Chirurgical Hospital, Philadelphia, etc. With 1,057 line drawings illustrating the text by John V. Alteneder. Third edition. Philadelphia and London: W. B. Saunders Company, 1907.

This third edition of Dr. Ashton's text-book maintains the good features of the first two editions, which received favorable notice in these columns, and in addition the following revisions and additions are to be noted. The total number of pages has been increased by twenty; thirty-two illustrations have been redrawn, seventy-one have been removed and eighty-two added, making a total of eleven more illustrations in the present work. In Chapter II, the method of collecting curette scrapings has been slightly improved, and in Chapter III, the blood in relation to surgery, there are evidences of a careful revision. Chapter VIII, on constipation, has been enlarged by three pages and four drawings illustrating "Colonic Lavage." The author describes his method of irrigating the colon, consisting of placing the patient in the knee-forehead position and using a nozzle having a large flange to prevent introducing it too far into the rectum and to facilitate holding it in place during the injection. Dudley's operation for cystocele takes the place of a combination of operations previously advised. The so-called Hirst's operation for vaginismus, a plastic on the fourchette, is introduced in the chapter on diseases of the vagina. Round ligament ventro-suspension of the uterus for retroversion with nine figures illustrating it has been added to Chapter XVI and ventral suspension has been left out.

The portion devoted to inversion has been improved by describing the operation for incision of the posterior lip of the cervix to reduce chronic inversion. It is a question whether the operation for amputation of an inverted uterus found on pages 373 and 374 is an improvement. We are glad to note that this edition has a competent chapter on chorio-epithelioma with the differential diagnosis from cancer. In the chapter on operative complications, under the heading of injuries of the intestines, Moynihan's end-to-end and lateral anastomosis operations are described and figured in minute detail, the anastomosis by means of the O'Hara and Laplace forceps found in the second edition being omitted. A chapter on passive incontinence of urine with Dudley's operation for its relief has been added, also details as to the sterilization of the patient's mouth as part of the preparation for anesthesia.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 18, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

HEALTH INSPECTION IN MASSACHUSETTS.

AN important step has been taken by Massachusetts in passing a law which now becomes effective, providing systematic medical inspection throughout the state. This law, which has been persistently and vigorously furthered by his Excellency Governor Guild, should be far reaching in its effects. The situation regarding public health becomes more complicated year by year with the development of industries and the tendency toward over-crowding, both at places of daily work, and also in the regions where the poorer portions of the population live. This new law will unquestionably supplement those already in force and particularly in relation to industrial conditions. It will be remembered that the governor in his inaugural address urged a closer study of sanitary conditions of factories, and he, as well as the community at large, now has the satisfaction of seeing the plan as originally outlined put into practice.

The state has been divided into fifteen districts, and the names of those appointed to be inspectors in these various districts have recently been made public. These appointments we publish in another place. They have evidently been made with much care, and only after conference with the officers of the State Board of Health, under whose supervision they are to work. The inspectors are expected to co-operate with the local health boards, and in the matter of factory inspection they are to supersede the district police. The act requires the appointment to each of the health districts of "one practical and discreet person, learned in the science of medicine and hygiene." The salaries are fixed in relation to the territory, the number of the inhabitants, character of the industries, and the amount of time required for the proper discharge of the duties connected with the inspection. We quote paragraphs from the act, giving the duties with which the inspectors are charged:

Every state inspector of health shall inform himself respecting the sanitary condition of his district and concerning all influences dangerous to the public health or threatening to affect the same; he shall gather all information possible concerning the prevalence of tuberculosis and other diseases dangerous to the public health within his district, shall disseminate knowledge as to the best methods of preventing the spread of such disease, and shall take such steps as, after consultation with the State Board of Health and the local state authorities, shall be deemed advisable for their eradication; he shall inform himself concerning the health of all minors employed in factories within his district, and, whenever he may deem it advisable or necessary, he shall call the ill health or physical unfitness of any minor to the attention of his or her parents or employers and of the State Board of Health.

The state inspectors of health shall be under the general supervision of the State Board of Health and shall perform such duties other than those hereby imposed upon them as the said board from time to time shall determine. They shall keep a record of their proceedings and observations, shall annually make a report of the same to said board on or before the thirty-first day of October, shall from time to time furnish said board with such information as it may require touching circumstances affecting the public health in their respective districts, and shall, in every instance, where written suggestions are made by them to the local authorities, send copies of such suggestions to said board.

This comprehensive scheme will be watched with much interest by the medical profession, sanitarians and all who are interested in safeguarding the public health. That certain abuses exist is not to be questioned, nor is it to be doubted that ignorance lies at the basis of many of the unfortunate conditions underlying our industries. The inspectors have before them a difficult piece of work, but one which faithfully and tactfully performed will redound much to their credit, as well as to that of the entire State.

DERMOID CYSTS OF THE ANTERIOR MEDIASTINUM.

DERMOID cysts of the anterior mediastinum are relatively rare, although Naudrot has been able to collect fifty instances which are published in his recent thesis. Although of congenital origin, these cysts clinically develop only at the time of

puberty, and it would seem that at this period they undergo a perturbation similar to that which manifests itself in the genital apparatus and breasts of the female. They rapidly and suddenly increase in size, their evolution ceases to be latent and the symptoms make their appearance.

The personal case reported by Naudrot shows that a thymic origin may be admitted, but the question of the pathogenesis of these tumors is far from being made evident and it still remains obscure for the majority of cases. Nothing authorizes the affirmation of one pathogenic interpretation to the detriment of another, and the theories expressed are quite as numerous as they are of little precision. At the most, one may say that, in general, these tumors represent true dermoid cysts arising from an epithelial or embryonal inclusion of blastomeric origin.

The clinical evolution offers nothing of special note and is that of all neoplasms of the mediastinum in general. Usually the first symptom which appears is a sort of progressive dyspnea occurring upon exertion. This dyspnea is, in the first place, well borne by the patient, but, after a time, a gradual and increasing aggravation of the symptoms takes place. Thoracic and intercostal pains appear accompanied by paroxysmal cough. In some cases a hemoptysis precedes the attacks of coughing. The expectoration may perhaps be more characteristic when the cyst opens into a bronchus. In the first place the quantity of the matter expectorated increases and may amount to as much as a pint in twenty-four hours. At the time that rupture of the cyst takes place, a more or less profuse vomiting occurs and, if a microscopical examination of the mucous or muco-purulent liquid is made, epithelial cells will be found similar to those composing the horny layer of the skin, as well as drops of fat and cholesterin crystals.

When hair is present it is a pathognomonic sign, and this is not infrequent since, out of fifty-six cases, it has been met with nine times. When once the pocket of the cyst is opened, expectoration becomes more abundant and hemorrhages recur frequently, and the patient will slowly die from asphyxia or cachexia, or rapidly from a hemorrhage. The evolution of the affection takes from three to eight years, often interspersed with periods of remission of variable duration, followed by paroxysms frequently due to an intercurrent complication.

The diagnosis which is impossible in the beginning of the process presents, with the exception of a few infrequent cases where a characteristic expectoration at once settles the question, extreme difficulty. Nevertheless, by an attentive clinical examination, completed by a radioscopic examination, one is able at least to diagnosticate the presence of a benign tumor on account of the persistency of the good general condition of the patient and the slowness of the evolution, although an exact diagnosis of dermoid cyst of the mediastinum may be lacking.

When once the diagnosis is made, surgical interference is necessary, and the chances of a successful result may be placed at about 70 per cent.

The operation should consist in doing an extensive thoracotomy, followed by pleurotomy. If the growth is found limited and not very large, its ablation may be attempted, but when the condition of affairs is the reverse one should merely evacuate as completely as possible the dermoid cavities and treat the pocket in a manner similar to other cysts of the body which cannot be enucleated.

RELIEF OF CONSUMPTIVES.

The report of the commission to investigate measures for the relief of consumptives in Massachusetts, the appointment of which was approved June 20, 1906, is now made public as Senate Document 330. The *personnel* of this commission, with Dr. Henry P. Walcott as chairman, and Dr. Charles F. Millet as secretary, is such as to insure results and conclusions of much significance. The work has been undertaken in most systematic fashion, the various counties being considered individually from a statistical standpoint and the allotment of cases at the Massachusetts State Sanatorium tabulated with relation to their respective cities and towns. The question of appropriate available sites for hospitals for tuberculosis, the cost of such hospitals, the advisability of the Commonwealth undertaking the care and treatment of these patients, together with sections on the nature, history, means of transference and prevention of the disease, are systematically and concisely considered. A practical portion of the report is a description of the shacks which may be used for outdoor care, details regarding diet and general hygiene and other means of helping consumptive persons in whatever stage of the disease they may be. Dr. J. H. Pratt's work in the formation of so-called tuberculosis classes is commented on most favorably and it is urged that the plan, as worked out by him, be widely imitated. The commission also hopes that much will be accomplished by the appoint-

ment of state medical inspectors, which is announced in this issue of the JOURNAL. The appointment of such inspectors, the commission holds, is far more important in the warfare against disease than the building of hospitals. The suggestions given in this section of the report may well be read by the new appointees in relation with their dealing with the subject of tuberculosis, which naturally will form a large part of their work. As an appendix a directory of institutions for the treatment of tuberculosis in Boston and vicinity is given. From this list one gets a better idea, perhaps, than in any other way, of the widely extended interest which has been aroused in the ways and means of combating the disease. The pamphlet, in general, forms an admirable *résumé* of the present state of the whole tuberculosis problem in this state, and should serve as a source of the greatest encouragement to those who may look with doubt on the prospect of final extermination of the disease. Nothing could be more striking in this connection than a chart at the beginning of the report, giving in graphic form the deaths from consumption in the thirty years from 1875 to 1905.

MEDICAL NOTES.

PURCHASE OF THE ST. LOUIS COURIER OF MEDICINE. — The *Interstate Medical Journal*, published in St. Louis, announces the purchase of the St. Louis *Courier of Medicine*, a journal established in 1879, and during its existence commanding a large following throughout the West and South. This is the fourth medical journal purchased and absorbed by the *Interstate Medical Journal* during the past few years.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 17, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 32, scarlatina 39, typhoid fever 20, measles 46, tuberculosis 83, smallpox 0.

The death-rate of the reported deaths for the week ending July 17, 1907, was 14.72.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, July 13, 1907, was 184, against 174 the corresponding week of last year, showing an increase of 10 deaths and making the death-rate for the week 15.74. Of this number 98 were males and 86 were females; 178 were white and 6 colored; 126 were born in the United States, 49 in foreign countries and 9 unknown; 36 were of American parentage, 114 of foreign parentage and 34 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 36 cases and 5 deaths; scarlatina, 28 cases and 3 deaths; typhoid fever, 15 cases and 3 deaths; measles, 46 cases and 3 deaths; tuberculosis, 51 cases and 15 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 15, whooping cough 1, heart disease 12, bronchitis 0 and marasmus 4. There were 16 deaths from violent causes. The number of children who died under one year was 33; the number under five years, 58. The number of persons who died over sixty years of age was 37. The deaths in public institutions were 67.

There were 6 cases and 2 deaths reported from cerebrospinal meningitis during the week.

AWARD OF THE WARREN TRIENNIAL PRIZE. — The Warren prize has this year been awarded to Dr. Aldo Perroncito of the University of Pavia, Italy, for an essay entitled, "*La rigenerazione dei nervi.*"

STATE BOARD IN DENTISTRY. — As the result of a recent examination held before the Massachusetts State Board of Registration in Dentistry, 41 out of 90 applicants passed successfully.

INVESTIGATION OF TUBERCULOSIS. — The General Assembly of Connecticut has, within a few days, authorized the governor to appoint a commission of nine to investigate tuberculosis in the state and to suggest means of preventing the spread of the disease.

PHYSIOLOGY IN SECONDARY SCHOOLS. — Dr. Eugene A. Darling, of the Department of Physiology in Harvard College, last week gave a lecture before the students in the summer school on "The Teaching of Physiology in Secondary Schools." Dr. Darling urged that attention be given to the principles of physiology late in their course in secondary schools instead of at the beginning. He urged further that the course be made more comprehensive and detailed, including laboratory work.

NEW YORK.

SUMMER SCHOOLS OF THE BOARD OF EDUCATION. — The usual summer schools of the board of education were opened for a term of six weeks on July 8. The registration was 11,440 in Man-

hattan and 8,170 in the Borough of Brooklyn. In connection with these vacation schools there are 63 playgrounds, and systematic instruction in gymnastic exercises is given in them. In addition, the board has opened several other playgrounds for the special use of mothers with infants and young children, and at these trained nurses are in attendance, to give instruction in the care and feeding of babies.

A New Commissioner of Street Cleaning. — The commissioner of street cleaning, Mr. Craven, having resigned, Mayor McClellan has appointed Dr. Walter Bensel, of the Health Department, to that responsible position. Dr. Bensel, who has for some years served very efficiently as sanitary superintendent, is unwilling to take the post permanently, as its duties would interfere too much with his other work, but has accepted the appointment for the period of three months.

Public Schools for Deaf Children. — The Board of Education has authorized the establishment of a permanent public school for deaf children, the first of its kind in New York, and it is to be opened in September in the school building in East Twenty-third Street, which has until now been occupied by the Stuyvesant High School and which can accommodate nearly two hundred pupils. In the report of the committee, which led to the inauguration of this new departure, it is stated that a day school for deaf children is entirely practicable, and it is advised that lip reading and oral speech should be taught exclusively. "A careful study of class instruction in different institutions, especially of the results found in the higher grades," the report says, "has convinced us that pupils taught exclusively by the lip method make better progress, have better trained minds and have greater confidence in themselves, than those taught in whole or in part by the manual method. As individual attention is absolutely necessary in the training of the deaf, it is advised that the classes should not consist of more than ten children, and it is further recommended that industrial work should form a prominent feature in the course of instruction.

Obituaries.

SIR WILLIAM HENRY PERKIN.

In the death of Sir William Henry Perkin, which occurred July 14 in London, at the age of sixty-nine, the world loses one of its great discoverers. His early education was in London at the City of London School, said to have been the only school in the country at that time where scientific subjects were taught. While still under twenty, he acted as assistant to Dr. A. W. Hofmann of the Royal College of Chemistry, and read the results of his first research one year later. In 1856, he made the discovery which has rendered his name famous through his experiments with aniline purple or mauve. He thereafter devoted his time to the development of his new discovery, which was destined to prove far reaching in its consequences. He formed a partnership with his father and brother and the new dye was successfully manufactured in 1857 and supplied to various dealers. He later discovered several other coal tar coloring matters, and in various ways rendered practical service in the manufacture of dyestuffs. He retired from technical work in 1873. In 1856 he was elected a fellow of the Chemical Society and of the Royal Society in 1866. He became president of the Chemical Society in 1883, after holding the position of one of the honorary secretaries for many years. He was president of the Society of Chemical Industry in 1884 and in 1885, and in 1891 received the honorary degree of Doctor of Laws from St. Andrew's and from Johns Hopkins. It will be remembered that last year the fiftieth anniversary of the original discovery of aniline purple was widely celebrated, both in England and in this country, and he himself was given due honor as the man who had done more than any other toward placing chemistry on a commercial basis. In Boston, Sir William was received with much ceremony, President Pritchett of the Massachusetts Institute of Technology presiding at a dinner, which was attended by many distinguished men, and at which an elaborate punch bowl was presented him.

SIR WILLIAM HENRY BROADBENT.

The death of Sir William Henry Broadbent, physician in ordinary to King Edward and the Prince of Wales, and long associated with the English royal family in a professional capacity, died in London, June 10. He was born in Yorkshire, England, in 1835, and after a preliminary education at Huddersfield College and Owens College, Manchester, graduated in medicine from the Royal School of Medicine in the same city. After further study on the Continent, he returned to England and established a large practice in London, in addition to giving much time to hospital work, medical societies and medical writing. He was at various times president of the Harveian Society of London, the Medical Society of London, and the Clinical and Neurological societies. He was twice censor of the Royal College of Physicians of London. In 1898, at the death of Sir Richard Quain, Dr. Broadbent was made physician extraordinary to Queen Victoria. In addition to his many other honors, he was a Knight Commander of the Victorian Order, a Commander of the Legion of Honor and a Fellow of the Royal

Society. He held the honorary degree of LL.D. from St. Andrew's and Edinburgh, and that of D.S. from Leeds. His medical interests were broad, but he was chiefly known for his writings on the circulation. He was one of the best representatives of the large cultivated and learned group of physicians which England has produced.

HAMILTON OSGOOD, M.D.

DR. HAMILTON OSGOOD, who for many years was an active practitioner of medicine in Boston, died in Oxford, England, July 10, in his sixty-ninth year. He had for some time past been broken in health and his death, therefore, was not unexpected. During the latter years of his active practice Dr. Osgood had made a special study of hypnotism in the treatment of disease, and, in fact, was one of the first to enter with enthusiasm upon the practice of suggestive therapeutics when it first came into popular notice in this country. His enthusiasm in the application of such methods of treatment possibly at times carried him too far, particularly in his estimate of the efficiency of hypnotic methods. It should not, however, be forgotten that he was one of the first to see the practical bearings of psychotherapeutic methods, and however extreme he may have been in carrying out his ideas, the courage of his convictions never failed. Dr. Osgood was a man of much versatility, a wide traveler and reader, and a suggestive writer upon the topics in which he was particularly interested. He was at one time on the staff of the BOSTON MEDICAL AND SURGICAL JOURNAL. He leaves a widow and two daughters, one of whom lives in London. Memorial services were held, July 14, in Dublin, N. H.

4. Dawes and Jackson have studied the action of sodium cacodylate, both experimentally and clinically, and conclude, contrary to the results of Fraser, that the drug is not without therapeutic value. Sodium cacodylate is an organic salt containing arsenic, and has been used hypodermically since 1899 as a substitute for inorganic arsenic, but since 1903 has fallen into disuse since Fraser's article maintaining that the drug did not liberate arsenic in the system, and that it had no physiological action. Dawes and Jackson find that after the hypodermic use of the cacodylate, inorganic arsenic appears in the urine and feces as well as in the tissues. Large doses were fatal to rabbits. Clinically the drug was used in 45 cases including anemias, Hodgkin's disease, chorea and skin diseases. The results, although apparently good, are not conclusive.

5. Muehlberg and Kramer describe a number of experiments performed, and determine certain points in the physiological action of ether and chloroform upon animals. The results are of value as scientific data, the clinical bearings of which are not entirely clear. Certain findings, however, are of practical interest. Ether given intravenously was found to be more toxic than chloroform, 2 minims being fatal in medium-sized rabbits. Amyl nitrite was found to have a distinct effect in counteracting the toxic effects of ether; its use is therefore advised in patients under anesthesia, to be begun as soon as the pulse begins to weaken. No corresponding beneficial action was observed in chloroform poisoning. No evidence was obtained of cardiac stimulation by ether; the experiments, on the contrary, showed that cardiac depression followed the administration of ether. The beneficial action of subcutaneous injections of ether in cases of shock, etc., is probably due to vasomotor stimulation.

9. Selby's article is a good summary of the important symptoms and signs of intestinal perforation in typhoid fever, with a plea for more general and more prompt surgical treatment. The mortality without operation is practically 100%; with operation of the 400 cases in literature, 25% have been saved, and a higher percentage of recoveries should be possible. The symptoms and signs are mentioned in the following order: pain and tenderness; the facies of agony and apprehension; shock and sweating; temperature falling and pulse rising; blood pressure at first low but soon rising above the former level; leukocytosis appearing 1 to 6 hours after the perforation; *muscle spasm*, the most valuable physical sign; increased thoracic respiration; distention with gas in the peritoneal cavity; nausea and vomiting. The differential diagnosis must exclude: appendicitis; suppurating mesenteric glands; intestinal obstruction; intestinal hemorrhage; iliac thrombosis, cholecystitis, diaphragmatic pleurisy and pneumonia. The aim, however, should not be definite diagnosis, but the recognition of the necessity for surgical treatment, which includes several other of the conditions mentioned. Hemorrhage may cause more or less pain; the onset of symptoms, however, is less acute than in perforation, and the blood pressure is lowered. When in doubt, the decision should favor perforation. Iliac thrombosis may be recognized by tenderness in the groin. The diagnosis of perforation can best be made by the physician in regular attendance upon the case, since comparison of present condition with preceding condition is essential.

[F. W. P.]

1. Petit in experiments made by injection of isotonic solutions into the peritoneal cavity in animals found that there was an afflux of polynuclear white blood cells to the spot of injection, and the resistance of the animal to infection was increased. He applied this fact by using sterilized horse serum as an injection, since this is the substance that produces polynucleosis most easily and usefully. After its use it was found possible to inject

lethal doses of cultures of *Bacterium coli* and *Staphylococcus pyogenes* into the serous cavities with impunity. This afflux takes place not only in the peritoneum, but also into the serous cavities, mucous membranes, and in wounds of all regions. More than a hundred cases in human beings have now been treated by injection of sterilized horse serum. In abdominal surgery of a non-septic character it has been used as a prophylactic, by pouring the serum into the cavity that has been opened, and drainage by gauze saturated with the serum. In septic cases it has been used by packing the cavity with gauze saturated with the serum, and pouring the serum into the cavity through the drain. The character of the pus changed at once; instead of a serous fluid it became thick and creamy and contained many polynuclears. Suppuration diminished rapidly and granulation began. In gynecology it was used in puerperal infections, after curetting, by packing the uterus with gauze saturated with serum, and placing dried serum in a small tampon introduced into the uterus. In phlegmonous infections and in burns it has been used, and the results have been excellent, healing being rapid. Healing and cicatrization have been obtained at once rapid and excellent; and cure has been obtained in desperate diseases. The method is one which aids the tissues in repair by putting them in a good condition for defence.

4. Arneill calls attention to the frequency with which on the one hand, diseases which surgery might relieve are treated medically to the end, and on the other hand, cases without organic disease are subjected to unwise surgery and made worse. To remedy the evils it is all important to give all possible attention to diagnosis, and where all other methods are inconclusive to resort to the exploratory incision. But when this is done and no definite cause for symptoms is found, the surgeon should refrain from operations such as gastro-enterostomy, for which there is no necessity. Cases are cited of pyloric obstruction and of hemorrhage where the results of surgical treatment were brilliant, and of gastric atony, enteroptosis, etc., where after operation the condition of the patient was no better than before. A brief description is given of the methods of diagnosis in stomach disorders, but on account of their fallibility a more common resort to the exploratory laparotomy is urged. [F. W. P.]

1. Trudeau's article describes the work which has been done in the treatment of tuberculosis by means of tuberculin. In spite of the lack of clinical evidence that tuberculosis produces a spontaneous immunity, much experimental evidence has been accumulated to show that an artificial immunity can be produced. This immunity must be due to antitoxins, antibodies, agglutinins, bacteriolysins or opsonins, the relative importance of which is as yet unknown. The immunity is produced artificially by means of cultures or culture products of the tubercle bacillus, from Koch's old tuberculin to the newer preparations, containing dead or living tubercle bacilli, human or bovine. The regulation of the dosage is important if good is to result rather than harm. Too large doses produce obvious ill effects; too small doses may fail in efficiency. For the regulation of the dosage there is as yet no established criterion. Wright has advocated regulation by the guidance of the opsonic index, according to which the dosage is extremely small. Trudeau, on the other hand, does not regard the production of opsonins as the sole end to be aimed at, and advocates conducting the treatment by careful observation of the clinical symptoms of the case, with the object of producing a clinical immunity to the tuberculin. He begins with small doses, 1000 mgm. of B. F., or Koch's B. E., increased progressively with each dose. The injections are given at first twice a week, later at somewhat longer intervals. The treatment is continued, usually for 6 months to a year, until finally 1 cc. of the undiluted preparation causes no reaction. The injections are then discontinued, to be resumed three to six months later. Throughout the course symptoms of intolerance, consisting in febrile reactions, local reactions, either at the site of the injection or at the site of the disease, or constitutional disturbances, such as malaise, headache, anorexia, and loss of weight and strength, must be watched for. If these appear, the treatment is discontinued until they cease, and then continued with more gradually increasing doses. Trudeau's experience has been mainly with chronic cases, with temperature under 100°. Acute febrile cases, he believes, should be treated by the rest and open-air method only. The clinical value of the tuberculin treatment is difficult to determine. Trudeau gives no statistics but expresses "a strong clinical impression . . . which has gradually become a conviction," the value of which no one can deny, that tuberculin immunization favorably influences the course of chronic tuberculosis.

2. Anders discusses the condition known as chronic polycythemia, or increase in number of the red blood corpuscles with cyanosis and usually enlargement of the spleen. He reports 3 original cases and analyses 18 cases from the literature, and suggests the theory that the cause is to be found in a venous stasis resulting from defective tonus of the veins. The symptoms are variable, but headaches, vertigo and neurasthenic symptoms are prominent. In treatment, the nitrites have given benefit in some cases. Begg reports a case where quinine in large doses seemed to have a distinct beneficial effect.

3. Barringer and Roper report the results of investigations in 17 cases in whose urine five years or more ago sugar was found on examination for insurance, and who were shown by further study to have not diabetes, but transient spontaneous glycosuria. Of these cases 50% showed an alimentary glycosuria at the end of five years, and 8 of the 17 have developed diabetes or probable diabetes. The remaining 50% showed no return of the glycosuria after its original discovery. The authors conclude that there is a class of cases of spontaneous glycosuria where the condition is quite harmless, contrary to von Noorden's view that a transitory glycosuria is in most cases a sign of developing diabetes. They regard the test of alimentary glycosuria as a valuable aid in distinguishing these cases of good prognosis. Where a small quantity of sugar is found in a patient's urine without

history of over-indulgence in sweets they advise a restricted diet and frequent testing of the reaction to glucose in the next six months. If the reactions are negative and the sugar does not reappear they believe that continuance of the restricted diet is unnecessary.

9. Coleman and Buxton, since their adoption of the ox-bile method of blood-culture for typhoid bacilli, have studied 34 cases, of which 10 proved by clinical course to be conditions other than typhoid, and the remainder unquestionably were typhoid. Of the 24 cases of typhoid, the bacilli were demonstrated by blood culture in all. From this and from the fact that published results of 33 different investigators, in spite of methods now considered faulty, show positive findings in 1,197 out of 1,602 cases, and in all stages of the disease, it is thought probable that the bacilli are present in the blood of every case of typhoid fever and throughout its course. The authors do not, however, regard the disease as a septicemia, but consider that the bacillemia merely represents an overflow of bacilli from the lymphopoietic organs. The methods of preparing the media and of identifying the organisms are concisely but clearly described. The value of the test as a method of early diagnosis is shown by the fact that in 391 published cases the bacilli were found 94 times when the Widal reaction was negative. [F. W. P.]

1. By an incision along the outer and inferior borders of the gland, Warren is able to reflect the breast inward toward the sternum, and thus gain access to tumors or cysts lying within its substance. These he removes by a V-shaped incision, without entering the cyst cavity. The remaining segments of the gland are then explored by a series of radiating incisions. Buried catgut sutures are used to unite the remaining breast tissue. This method of approach leaves a scar which in no way interferes with the subsequent cosmetic appearance of the gland. It is so placed, however, that if evidence of malignancy be found it may easily be prolonged into the usual incision for amputation of the gland with dissection of the axilla. The article is admirably illustrated.

2. Mayo calls attention to the two varieties of gastric and duodenal ulcer: (1) the indurated or calloused ulcer, which can be seen and felt during operation on account of the cicatricial tissue, which gives the appearance and feel of a scar from the outside of the stomach wall; and (2) the non-indurated, mucous ulcer which does not betray its presence by thickening or other sign, and is usually located with much difficulty, even if the stomach and duodenum be opened and careful search be made. All the positive advances in surgical knowledge concern the first group. That ulcers of the second type exist in both acute and chronic form is not to be doubted, but at the present time Mayo does not consider that a diagnosis of mucous or other undemonstrated ulcer indicates a surgical operation, unless there exist complications, such as perforation, hemorrhage or obstruction. Indurated ulcer occurs fully as often in the duodenum as in the stomach. Seventy-seven per cent of the cases of duodenal ulcer occurred in men. In 54% of the cases of cancer of the stomach, there was conclusive evidence that the cancer had its origin in ulcer. The best means of identifying the pylorus is by the pyloric vein, which extends from the inferior margin of the pylorus on the gastric side, upward and across about three fourths of its extent. From the superior margin a similar vein extends downward, until it nearly or quite meets the one from below.

3. Munro reports the results of 150 cases of benign lesions of the stomach. Eighty-seven of these showed gross ulcers in the stomach, in the duodenum, or in both; 25 showed well marked adhesions without evidence of an active ulcer; 16 cases belonged to the class of so-called medical ulcer, without palpable lesion; 15 were cases of so-called neuroses, and 9 were classed variously as ptosis, spasm of the pylorus, etc. In the majority of cases of gross lesion the benefit from operation was immediate and permanent. The "medical ulcer" cases were only very slightly or not at all benefited by operation, so that Munro advises closing the abdomen when there is no gross ulcer, pyloric obstruction, or other crippling lesion to be found. The worst subjects for interference were those classed as neurotics, most of such cases being made worse by operation.

4. Coffey employs the following procedure in the closure of fecal fistulæ: (1) Dissect out the old scar down to the fat, and make an incision around the fistulous tract, including a small strip of skin, directing the point of the knife slightly away from the fistula, so that it first comes in contact with the fascia about half an inch away from the fistula, in order to avoid any possibility of opening the peritoneum. (2) Dissect up the fat from the fascia for as much as two inches from the incision; draw it back; clean off the fascia. (3) Make an incision through the fascia, beginning at the upper end of the wound, and coming toward the fistula. Dissect the fascia from the muscle for at least two inches in every direction. (4) Dissect the muscle from the peritoneum in the same manner, so that the peritoneum hangs loosely, with the fistula standing up in its center. (5) Trim off the little margin of skin which has been left with the edge of the fistula. (6) The edges of the fistula are turned in with linen sutures knotted on the inside. (7) If the wall of the fistula is hard and cicatricial, making it difficult to turn in, it is well to make an incision part way through this cicatricial tissue. (8) A second layer of sutures is placed above the turned-in fistula, and the wound thoroughly cleaned with salt solution. (9) Silkworm gut sutures are passed through skin, fat, fascia and muscle, about a half inch or more from the edge, and left untied, space being left at the upper end of the wound for drainage. (10) Suture the muscle loosely with catgut. (11) Suture the fascia with strong double catgut. (12) Suture the skin with horsehair. (13) Place the drains, either tubes or cigarette wicks, and tie the silkworm-gut sutures over gauze rolls. The lateral spaces between the fat, fascia and muscle serve as drainage channels to conduct any septic fluid around the line of suture to the drain at the upper end of the wound. The colored illustrations accompanying the article are of value in showing the various steps.

7. McWilliams concludes as follows: (1) Primary, acute and chronic typhlitis occurs independently of appendicitis, dysentery, tuberculosis, actinomycosis or cancer, and is idiopathic in origin, or depends on coprostasis. (2) Primary typhlitis, the appendix being normal, may lead to perforation, with the formation of perityphlitic abscess or general peritonitis. (3) The symptoms of primary typhlitis are usually identical with those of appendicitis, and the indications for operation are similar in the two conditions. (4) Primary typhlitis is rare in comparison with appendicitis. (5) The danger of a primary typhlitis consists in the liability to the rupture of an ulcer, and to the development of appendicitis. (6) Purgatives are contra-indicated in inflammations of the right iliac

fossa. (7) The treatment consists of laparotomy, removal of the appendix, closure of any perforation, or invagination of any suspected spot in the cecal wall, with removal of a piece for microscopical examination if it is thought necessary.

8. Bodine, basing his statement on over 400 operations for radical cure of inguinal hernia, advocates the use of local analgesia in all such cases. He uses a 1 to 500 warm cocain solution.

10. Jacobson states that the subject of nephritis dependent upon surgical conditions located remotely from the kidneys is one to which sufficient attention has not been given by the profession. He reports three cases. In the first there was present a bacterial or toxic nephritis dependent upon a septic condition (sloughing fibroids) and associated with other evidences of profound sepsis, especially endocarditis. The patient's condition was precarious, and yet after the expulsion of the fibroids and the subsidence of the sepsis of the uterus there was at once a prompt recovery from the secondary disturbance, both in the heart and kidneys. In the second case, one of intestinal obstruction from adhesions and bands, a toxic condition was created within the intestinal tract, and as a result of this toxemia a pure toxic nephritis. After relief of the intestinal obstruction, though the patient nearly died of uremic convulsions, the nephritis gradually improved and recovery ensued. In the third case there was present pancreatitis due to cholecystitis. The resulting toxic condition caused both nephritis and glycosuria, both of which were recovered from on draining the gall bladder. These cases illustrate a type in which the bacterial or toxic nephritis, instead of being a contra-indication to operation, becomes a most positive indication for operation, as by such a course only can it be removed.

12. Keyes's paper is based on the observation of 100 patients bearing 153 tubercular testicles. He finds that (1) testicular tuberculosis is clinically never an isolated lesion. It is only one feature of a general genital tuberculosis, for (2) sterility is frequent if not constant at the time the first testis is invaded; (3) there is evidence at this time of inflammation of the internal genitals; (4) relapse in the opposite testicle occurs within a few years, in eight or nine out of ten cases, and (5) such relapse is in no wise postponed by early removal of the diseased testis; (6) moreover, though suppuration seems often to result in permanent cure of the local process, and (7) though a chronic focus several years old is likely to suppurate, yet (8) in no case can one feel certain of a real cure unless the tubercular epididymitis has been removed; (9) the demoralizing effect of epididymectomy is not to be compared with that of castration, and (10) slight tuberculosis of the testis may be depended upon to heal spontaneously after removal of the epididymis; (11) hence epididymectomy is the radical operation of choice, unless there is hyperacute generalized epididymo-orchitis, or unless the testis is destroyed by suppuration; (12) this operation has a beneficial effect upon the general health and upon tuberculosis of the internal genitals; (13) it should, therefore, be performed early in the disease; (14) this in spite of the fact that tuberculosis of the testis is often but an insignificant part of a generalized progressive tuberculosis, or (15) is for many years the only active lesion of the disease; (16) if the patient is sterile, it would probably be wise to remove both epididymes, even though only one side is diseased. [W. C. Q.]

THE LANCET.

7. MERIUR, C. *Meditations on Gout* (written during an attack).

2. Ehrlich's first lecture is a dissertation on immunity, with especial reference to the relations existing between the distribution and action of antigens and antibodies. It is as clear as this somewhat complex subject can be made.

3. For cardiac dilatation with sudden broken compensation Duckworth advises venesection of 6 to 8 oz., or leeching; next, purgation for which he considers mercury by far the best agent, then digitalis. A dry diet is very important. Tapping should be resorted to if necessary.

4. Mummery advises the use of the sigmoidoscope in all obscure cases of colitis. He reports 36 cases, and takes up the various causes of this condition, both outside and inside the intestines. For treatment, he uses irrigation with a douche, the reservoir of which is never higher than 1 to 2 ft. above the anus. In acute conditions he advises using mild non-irritating solutions. In ulcerated cases large olive oil injections are of benefit. In cases in which no cause can be found in prolonged examination, and which do not yield to careful medical treatment, he advises operative measures and a thorough examination of the intestines. [J. B. H.]

BRITISH MEDICAL JOURNAL.
JUNE 15, 1907.

1. BROADBENT, W. H. *Remarks on Some Affections of Speech.*

7. FELKIN, H. G. *A Contribution to the Value of Complete Vocal Rest as an Aid to Recovery from Laryngeal Tuberculosis and Allied Conditions during Sanatorium Treatment.*

2. Mackenzie considers lumbar puncture of the greatest value in all forms of meningitis and thinks that he has saved several lives by this process. In the case he reports, nearly 9 oz. of fluid were obtained by nine punctures. The vaccine used in his case was prepared from the organisms obtained from culture of the fluid. While convinced of the value of lumbar puncture he is unable to state how much good was done by the use of the vaccine.

5. "Congenital hypotonia," or "myatonia congenita," is a rare condition, consisting of excessive muscular laxness and weakness. Coombs's case was in an otherwise healthy girl of ten years. The condition was present from birth, yet could not be ascribed to any hereditary cause. Unlike most muscular dystrophies, it has not occurred in any other members of the patient's family. The muscles are weak in proportion as they are small and short; there are no sensory or trophic changes, no fibrillary tremor, and no reaction of degeneration. The small size of the muscles is due not to atrophy, but to a lack of development. All the muscles in the body are implicated. There seems to be a rounding of the articular surfaces as shown by x-ray, which accounts for some of the abnormal mobility. As in myasthenia gravis there is apt to be a persistence of the thymus. Oppenheim considers the prognosis favorable. [J. B. H.]

9. GUTMANN, A. *External Eye Diseases and Their Relation to Disorders in the Nose.* (Concluded.)

1. These authors report a series of 11 cases of syphilis treated by atoxyl and conclude that it has an unmistakable good effect when used in sufficiently large doses; it is especially beneficial in the malignant forms. They injected intramuscularly 10 cases with a 10% solution and one with a 15% solution. The injections were of 0.2 to 0.6 gm. every two days at first, later every three days. It caused no local disturbances. It makes a very important addition to our means of combating syphilis in those cases which have an idiosyncrasy against the mercury and iodide treatment.

2. Schmorl has obtained good results in staining sections by the Giemsa method by selecting thin frozen sections previously fixed in 4% formalin, and staining after the Giemsa method, allowing the stain to be in contact with the section for one hour, then using a fresh solution of the stain and allowing it to stand for 12 or, better, 24 hours.

12. LENGFELLNER, K. *A Steel Spring for Flat Foot Pads.*
13. *TREUPEL, G. *The Present Status of Percussion of the Heart.* (Concluded.)

1. During the last few years there has been a slight but distinct rise in Prussia in the mortality from puerperal fever. This, according to Herff, is to be laid at the door of the physician and not of the midwives. The causes are twofold, viz.: insufficient disinfection of the hands and too much operating. One of the chief reasons for carelessness in disinfecting the hands is the complexity of modern methods. This difficulty has been obviated in his clinic by the use of Ahlfeld's hot-water alcohol method. Out of 6,000 deliveries in his clinic the mortality from puerperal fever was only .08% and no cases were infected in the hospital. It is important to operate only on strict indications and to make as few pelvic examinations as possible.

2. Recent work on the streptococcus, and especially in its relation to immunity, make it probable that there is only one form of streptococcus and that the variations shown are merely the effects of environment. Zangemeister shows that the streptococci often found in the vaginal secretion of healthy women can be made pathogenic for animals, and that immune sera acquired in this way will protect against infection with other varieties of streptococci. There is, therefore, the possibility that puerperal fever may arise from infection with such organisms, but it has been clearly shown that the vast majority of infections are due to germs introduced from without.

4. Moro describes a method devised by him for the demonstration of alexin, requiring only a few drops of blood. For the details the reader is referred to the original article.

6. The dorsal foot reflex consists in the movement of the toes on tapping the outer part of the dorsum of the foot with a percussion hammer. Normally the toes (excepting the great toe) are extended, but in disease a plantar flexion may occur. Lissmann confirms the observations of the two describers of the reflex, Bechterew and Mendel, finding it positive (*i. e.*, plantar flexion) only in cases with positive Babinski's sign, and absent altogether in anterior poliomyelitis. He also found in infancy the reflex positive in all cases with positive Babinski. The significance of this sign is therefore identical with that of Babinski's, indicating (except in infants) disturbance of conduction in the pyramidal tract.

7. Döderlein has shown that the contamination of the operative field from the invasion of bacteria from the neighboring skin may be prevented in the following way: the skin is cleaned before operation with a formalin-benzin mixture, painted with iodine and then covered with a sterile solution of rubber in forman-benzin, which sticks to the skin and forms an impervious layer over it. Littauer reports excellent results from the use of this "gaudinin" in abdominal operations.

9. In a typical case of multiple neurotic gangrene of the skin Szöllösy produced a similar lesion on the back of the hand by suggestion, telling the patient, while she was under hypnosis, that it would appear the next day. The patient had no memory of what had occurred, but the sore appeared as predicted.

13. Treupel finds that three precussion methods give the most accurate projection of the heart's outline, viz.: (1) the Goldscheider very light percussion (Schwellenswert percussion); (2) the medium heavy percussion according to Moritz; (3) the Ebstein resistance percussion (Tast percussion). All of these gave results agreeing closely with those obtained with the orthodiagraph; the Goldscheider method was, however, the most accurate. He considers that all three have their places and are useful as checks on one another.

[W. T.]

8. MAGNUS, LEVY A. *Account of a Trip to Russia.*

1. In two cases of gun-shot wound of the thorax, the existence of tenderness and abdominal spasm led Hildebrand to open the abdomen, but he found no lesions there. A third case presented the same signs and the autopsy showed that the abdominal organs were intact. The cause of the pain and spasm proved to be irritation of the lower intercostal nerves by the bullet, the skin and muscles of the abdomen being supplied by the six lower intercostal nerves. The cases were all penetrating wounds in which the bullet entered near the heart and became lodged in the lower intercostal spaces behind. The practical lesson from these observations is that in the case of gun-shot wounds of the thorax abdominal pain and spasm do not necessarily mean injury to the abdominal viscera.

5. The chief defect of the various sera used against typhoid fever has been that the principal action has been bacteriolytic and not antitoxic, and the destruction of the bacilli has overwhelmed the organisms with the endotoxins which were set free. Meyer and Bergell have succeeded in obtaining an endotoxin from typhoid cultures, which kills laboratory animals in a short time. If smaller doses

are employed, the animals die after a few days, with diarrhea, prostration and finally convulsions; the post-mortem examination shows intestinal lesions like those of man, but no enlargement of the spleen. It is, therefore, probable that many of the symptoms of typhoid fever are purely toxic, while others are due to the bacteriemia. By inoculating horses the authors have obtained a serum which is distinctly antitoxic as well as bacteriolytic and exerting marked curative and prophylactic properties in animals. The serum is somewhat weak for use in man, but will probably be susceptible of improvement.

Correspondence.

LETTER FROM CHINA.

Climate and Diseases in Shanghai and Canton. Medical Practice.

Manila, May, 1907.

Mr. Editor: Since my letter to you from Japan, I have spent more than two months in China, having landed in Shanghai just before Christmas and sailed from Hongkong in March. Excepting a few mild, sunny days, the winter climate of Shanghai is not a pleasant one. It thaws nearly every day, but the sun may not shine for weeks and a raw wind sweeps up the Yangtse from the sea, searches every corner of the city and penetrates to one's vital organs. Owing to the slight degree of elevation and the remarkable flatness of that part of China, the frequent February rains and the scant sunshine, there is mud and water everywhere. The houses, warmed only by open fires, are often cold. These conditions would seem at first sight to favor colds, bronchitis and pneumonia, but among the English residents who constitute the majority of foreigners in Shanghai colds and bronchitis are infrequent. This may be because the temperature changes in Shanghai are not very frequent or extreme; or it may be due in part to two other facts, namely: that owing to the coolness within and the moderate cold without, the interchange of air through window cracks is less rapid, and because the skin is never damp with perspiration, one is less sensitive to draughts. I was reminded of the remark of an experienced physician: "People do not take cold, they take hot."

The winter climate of Hongkong is somewhat like that of Shanghai but much milder. That of Peking is entirely different, as might be expected from its inland situation.

The sun shines there day after day, from a cloudless sky. The air is brisk, thaws are unusual and it rarely snows. The thirsty wind from the Mongolian desert absorbs every atom of moisture, leaving the surface soil too dry to freeze; hence the dust-storms which occasionally occur at this season. The dryness of the air affects the skin of the body and limbs making it harsh and causing pruritus. Just as in a New England winter when the northwest wind clears the sky, the dry air sparkles and the temperature is low, one feels that he must rush into the open and take violent exercise, so in Peking such weather is tremendously stimulating. But in Peking it lasts almost without intermission for months and the opportunities there for out-door sports are limited. Consequently, nervous tension is great. Insomnia is spoken of by the residents and is a common complaint of visitors. Nevertheless, and in spite of the unusual quantities of street dust, which get into the air passages, there is little infectious disease in Peking in the winter. Perhaps the bacteria of the street wither away and die, as did the seed which fell upon the rock. Last January, however, there was a widespread epidemic of whooping-cough among children and some cases were fatal.

The winter, until the middle of January, having been even drier than usual, and fearing that by frost getting deep into the ground crops would be delayed, the Emperor, not daunted by a cloudless sky, prayed for snow. When I arrived in Peking the sun was obscured, the clouds broke on the second day, and on the third came rain and sleet. Men said it was a bad omen, that "the earth had taken on a coat of mail." The Emperor prayed again; threatening clouds hung low for a week, then a little snow fell. But the high priests were not satisfied, and when I left Peking his Celestial Holiness was about to pray once more. Bad weather followed me to Hankow and it snowed on the Yangtse.

The ordinary run of hospital cases in Shanghai in the winter is of no special interest, but there are a few cases of Malta fever or liver abscess. Beri-beri is common there in summer among the Chinese, but is not seen at all in winter. In Hongkong it is found the year round and in summer hundreds of cases are treated in the hospitals. The Tung-wa Hospital in Hongkong is run and maintained by Chinese for their own people. There were thirty odd cases of beri-beri there in March. The resident, Dr. Jew Hawk, is a Chinese trained in the United States. He said that 40% of the beri-beri cases admitted to the hospital died (mild cases do not come in), and that of those who recover some have recurrences in a short time. He had not observed recurrence yearly at the same period. He considers the extreme dampness in the summer in Hongkong to be an important etiological factor. The winter climate there is by no means a dry one, but the cold weather seems to check the disease. The patients in the Yung-wa may be treated as they prefer, by Dr. Jew Hawk on modern lines, or by others who prescribe the time-honored remedies of China. If the neuritic pain of beri-beri is severe they always get transferred where they will receive morphine. The beds which the Chinese prefer are low wooden tables covered with a thin mat of straw. A Chinese woman on entrance to a European hospital was laid upon a spring bed. When she turned over and felt the mattress give she clutched the sides of the bed in terror, fearing that she would fall, and thereafter slept upon the floor.

At the Government Civil Hospital, also in Hongkong, I saw several obscure cases of fever. One of them of short duration had an urticarial eruption on the skin and distoma eggs in the stools. A second patient, who had had slight fever and paresis of one arm for weeks, had taken iodide all the time with little improvement, and a third, a native of India, had a chronic wasting disease, with recurrent fever, jaundice and enlarged liver and spleen. The spleen was not nearly as large as is usual in kola-azar. Malignant disease seemed the most probable diagnosis. It was most interesting to see and discuss these cases with the resident, Dr. Koch.

Shortly before I left Boston, a friend said to me: "Why don't you start a firm of doctors, including physician, surgeon and specialists? I will pay you so much a year to keep me in good health, as they do in China." In Honolulu there is at least one firm of doctors, and in Shanghai and Hongkong all the English physicians belong to firms. There are usually four partners. Every man in turn goes home for one year in every four and has the opportunity to see what is being done there. His practice is taken up by the other members and the absentee receives his percentage of the profits at regular intervals. The fees in Shanghai are so much a year for each member of the family. The patient may choose any doctor in the firm as his physician and call in any of them for consultation, or when his physician is away. From the patient's point of view the system saves trouble, a doctor can be found at any time and, most important of all, it is a sort of insurance policy, because when there is much sickness in the family the doctor's bills do not increase. From the physician's standpoint it is a success because he gets an assured income, which he can estimate and it enables him to return home every few years without losing his patients. In Shanghai it is agreed that every man shall take complete charge of his patients. If an operation is required he shall do it and if special treatment is necessary he must give it. He may, of course, consult his colleagues. The system in Hongkong is different. The partners divide the classes of work as far as possible among each other and they charge fees for every visit, but profits are divided as at Shanghai. If a man wishes to join the firm he must first serve satisfactorily for two years gratis. Pure specialists are unknown in these cities and probably they will not appear there until the communities are larger than now. When they do come the firms in Shanghai will have to make some concessions. It is an interesting question whether or not such firms could be run smoothly in a city where there are nine or ten well-established specialties.

Very truly yours,

George C. Shattuck, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JULY 6, 1907.

CITIES.	Reported deaths in each.	Deaths under five years.	CITIES.	Reported deaths in each.	Deaths under five years.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING JULY 13, 1907.

J. T. MILLER, assistant surgeon. To the "Rhode Island."

C. T. GRAYSON, assistant surgeon. Ordered to the Bureau of Medicine and Surgery, Navy Department.

P. M. RIXEY, medical director. Commissioned medical director from May 7, 1907.

R. C. HOLCOMB, surgeon. Commissioned surgeon from Dec. 17, 1905.

J. T. KENNEDY, surgeon. Commissioned surgeon from May 7, 1907.

F. M. MUNSON, passed assistant surgeon. Commissioned passed assistant surgeon from April 5, 1906.

R. G. HEINER, passed assistant surgeon. Commissioned passed assistant surgeon from Dec. 26, 1906.

H. L. BROWN, passed assistant surgeon. Commissioned passed assistant surgeon from April 12, 1907.

O. J. MINK, passed assistant surgeon. Commissioned passed assistant surgeon from June 7, 1907.

O. V. HUFFMAN, assistant surgeon. Ordered to the Naval Hospital, Boston, Mass.

G. B. TRIBLE, assistant surgeon. Ordered to the Naval Hospital, Norfolk, Va., July 30.

H. A. GARRISON, assistant surgeon. Ordered to the Naval Hospital, Newport, R. I.

M. E. ROSE, assistant surgeon. Ordered to the Naval Hospital, New York, N. Y.

G. P. LUMSDEN, medical inspector. Detached from the Naval Recruiting Station, Indianapolis, and ordered to command the Naval Hospital, Pensacola, Fla.

F. S. NASH, surgeon. Detached from command of the Naval Hospital, Canacao, P. I. Home and wait orders.

L. W. BISHOP, passed assistant surgeon. Detached from the "Iowa" and granted leave for one month.

W. J. ZELESKY, passed assistant surgeon. Detached from duty with the third torpedo flotilla, on board the "Stringham," and ordered home to wait orders.

J. D. MANCHESTER, passed assistant surgeon. Detached from the Naval Hospital, Philadelphia; to the Naval Hospital, Pensacola.

M. C. BAKER, acting assistant surgeon. Detached from the "Franklin" and ordered to Midway Islands, sailing from San Francisco, Cal., about July 25.

D. H. CASTO, acting assistant surgeon. Ordered to the Naval Recruiting Station, Indianapolis, Ind.

M. DONELSON, acting assistant surgeon. Ordered to duty with the third torpedo flotilla, on board the "Stringham."

F. D. CHAPPELEAR, acting assistant surgeon. Detached from the Naval Hospital, Pensacola, and ordered home to wait orders.

G. L. WICKES, assistant surgeon. Detached from the "Wilmington" and ordered to the "Cincinnati."

F. E. SELLERS, assistant surgeon. Detached from the "Cincinnati" and ordered to the "Wilmington."

P. J. WALDNER, pharmacist. Appointed pharmacist from July 3, 1907.

APPOINTMENTS.

THE following physicians have been appointed state health inspectors: District 1, Charles G. Morse, Wareham. District 2, Adam G. MacKnight, Fall River. District 3, Wallace C. Keith, Brockton. District 4, Elliott Washburn, Taunton. District 5, Harry Linenthal, Boston. District 6, Albert P. Norris, Cambridge. District 7, William Voss, Beverly. District 8, William Hall Coon, Lawrence. District 9, Charles E. Simpson, Lowell. District 10, William W. Walcott, Natick. District 11, Melvin G. Overlock, Worcester. District 12, Lewis Fish, Fitchburg. District 13, Harvey T. Shores, Northampton. District 14, Richard S. Benner, Springfield. District 15, Lyman A. Jones, North Adams.

RECENT DEATH.

HAMILTON OSGOOD, M.D., M.M.S.S., of Boston, died in Oxford, England, July 10, 1907, aged sixty-nine years.

BOOKS AND PAMPHLETS RECEIVED.

The Technic of Operations upon the Intestines and Stomach. By Alfred H. Gould, M.D. Illustrated. Philadelphia and London: W. B. Saunders Co. 1906.

A Text-Book of Obstetrics. By Barton Cooke Hirst, M.D. Fifth edition, revised and enlarged. Illustrated. Philadelphia and London: W. B. Saunders Co. 1906.

Diet in Health and Disease. By Julius Friedenwald, M.D., and John Ruhräh, M.D. Second edition, thoroughly revised and enlarged. Philadelphia and London. W. B. Saunders Co. 1906.

Photoscopy (Skiascopy or Retinoscopy). By Mark D. Stevenson, M.D. Illustrated. Philadelphia and London: W. B. Saunders Co. 1906.

A Manual of Diseases of the Nose, Throat and Ear. By E. B. Gleason, M.D., LL.D. Illustrated. Philadelphia and London. W. B. Saunders Co. 1907.

A Laboratory Manual of Invertebrate Zoölogy. By Gilman A. Drew, Ph.D. Philadelphia and London: W. B. Saunders Co. 1907.

Publications of the Massachusetts General Hospital, Boston. Selected Papers by the Staff. Vol. I, No. 3. June, 1907.

Thirtieth Annual Report of the Managers of the Adams Nervine Asylum. Boston. 1907.

Thirty-sixth Annual Report of the Trustees of the City Hospital of the City of Worcester for the Year Ending November 30, 1906.

Lea's Series of Pocket Text-Books. Materia Medica, Therapeutics, Pharmacology and Pharmacognosy, including Medical Pharmacy, Prescription Writing and Medical Latin. By William Schleif, Ph.G., M.D. Series edited by Bern B. Gallaudet, M.D. Third edition, revised and enlarged. Philadelphia and New York: Lea Brothers & Co. 1907.

A Text-Book on the Practice of Gynecology. For Practitioners and Students. By William Easterly Ashton, M.D., LL.D. Third edition, revised and enlarged. Illustrated. Philadelphia and London: W. B. Saunders Co. 1907.

Gynecology and Abdominal Surgery. Edited by Howard A. Kelly, M.D., F.R.C.S. (Hon. Edin.), and Charles P. Noble, M.D., Vol. I. Illustrated. Philadelphia and London: W. B. Saunders Co. 1907.

Abdominal Operations. By B. G. A. Moynihan, M.S. (London), F.R.C.S. Second edition, thoroughly revised. Philadelphia and London: W. B. Saunders Co. 1906.

Atlas and Text-Book of Human Anatomy. By Dr. Johannes Sobotta. Edited, with additions, by J. Playfair McMurrich, A.M., Ph.D. Illustrated. Vols. I and II. Philadelphia and London: W. B. Saunders Co. 1906.

A Treatise on Surgery. By George Ryerson Fowler, M.D. Illustrated. Vol. II. Philadelphia and London: W. B. Saunders Co. 1907.

HYDROPHOBIA AND ITS PREVENTION.*

BY C. P. SYLVESTER, M.D., BOSTON.

IN 1856 a committee appointed by the American Medical Association to investigate the subject of rabies presented a paper on "Hydrophobia, Its Origin and Development," which was read at the meeting in Detroit in May of that year, by Dr. Thomas Blatchford.[1] In it he reported 106 human deaths, the first seven cases having been furnished him through the kindness of Drs. J. B. S. Jackson and C. B. Homans, of Boston. The cases were not all the committee could find in this country, but were deemed enough to make out justification for legislation, and a copy of that report was sent to the governor of each state.

In the preface was this question: "Shall human *or* canine life be protected by the ægis of the law?" The silent evasion of this question since 1856, when Germany had already answered it and acted, although intended to protect the dog, has protected neither dog nor man. It has caused the death of at least several thousand persons in the United States, and naturally a great many more dogs.

We are believed by pet animal owners and others to be cold-hearted and brutal when we attempt to correct legislative deficiencies which allow the lives of scores of children to be sacrificed annually by the most horrible death known. The opponents of such legislation have been able to prevent the scientific enactment of laws principally through general ignorance as to the existence, origin, contagiousness and frequency of the disease.

That some members of the medical profession are loath to give up the traditions of our ancestors regarding the disease has been demonstrated to me by the comparison of their ideas now with those expressed seven years ago, when I first wrote on the subject of rabies. The layman must get his knowledge of sanitary science through the physician.

Rabies is an acute disease of all warm-blooded animals, caused by a specific germ and communicated by inoculation to man. The disease is prevalent everywhere, with the exception of a few places where it has never been imported. There are many references to it in early literature, its mysterious appearance and awful character inspiring the superstitious writers of that time.

It was accurately described in an ancient Hindu work, written by a physician named Susruta one thousand years B.C. Homer, in the ninth book of the Iliad, compares the fury of Hector to the rage of a mad dog, and Aristotle in 322 B.C. described it. To him is due the existing fallacy that it is fatal to every creature bitten but man.

Lucanus in his poem "Pharsalia," in about 60 A.D., wrote: "The poison kills, the bite conveys it, death lurks in the teeth."

*Read before the Boston Society for Medical Improvement, March 19, 1907, and before the clinical section of the Suffolk District Medical Society held in conjunction with the Boston Medical Library Meeting, May 1, 1907.

The origin of the disease in man is practically always associated with dogs, yet it may be caused by bite of any animal. The bite of a cow has caused it. The Duke of Richmond, former Governor of Canada, contracted the disease from the bite of a captive fox. Very rarely does one person contract it from another, the germ being attenuated by its passage through man. Human saliva inoculated into a dog has developed the disease. The dog and also all carnivera are potent attenuators of the germ with lengthening of the period of incubation. All herbivera intensify the germ. The rabbit, being a marked intensifier, shortens, by the successive passage of the virus through several of them, the period of incubation from three weeks to six or seven days, which gives us the "fixed virus" of Pasteur used for the preparatson for his vaccine. With the intensification or attenuation of the virus goes respectively a greater or lesser distribution of the cause of the disease in the nervous system and a more marked or slighter rabies of the convulsive form, as will be explained later.

Rabies occurs during all the months of the year, but is perhaps a little more prevalent during April, May, June and July.

There is no doubt but that the apparent period of incubation can vary exceedingly. The period may be as short as one week or longer than one year. Most cases develop in from three to seven weeks. In 144 cases carefully observed by Renault, LeBlanc, Saint-Cyr and Peuch[2] the incubation period was 100 to 120 days in four cases; 80 to 90 days in seven cases; 70 to 75 days in five cases; 365 days in one case.

Fifty-seven per cent did not develop the disease until after thirty days. This apparent variable period of incubation, however, consists probably of an incubation period as constant as that of small-pox, but with a most variable pre-incubation period on account of the irregularity with which the germs are conveyed to their seat of development. The so-called incubation period in man may likewise vary as widely. The infectiveness of the disease in man depends even more upon the stage of the disease in which the rabic animal is than the situation of the wounds. The virus is quantitative rather than qualitative, and lacerated uncovered parts would naturally receive more saliva than where the clothes could absorb it, and the head and neck lacerations not only being unprotected by clothing, but being so much nearer the seat of development of the disease, give a higher mortality, with shorter period of incubation, than covered wounded parts more distant. The mortality, however, may vary from *nil* to 100% without regard to the situation of the wounds. I have seen the records of two rabic dogs where five persons in each case were bitten. All ten persons died of hydrophobia. What was the reason for this very exceptional mortality? Let us trace the mode and route of development of the rabies germ and see.

That the germ develops in nerve tissue there is no doubt, for there is no part of the nerve tissue that has not been found infective. But the nerve

tissues are never found virulent until the end of the incubation period, and then the infectiveness increases markedly as the cerebrospinal axis is approached. In other words, the nidus of infection is not at the periphery as in tetanus, but in the cerebrospinal substance, and, therefore, it is probably not, as is tetanus, an ascending neuritis.

That it is a descending neuritis, after developing in the central nervous system, there is sufficient proof. How is the nidus of infection transferred to the brain?

Pasteur has shown that intravenous injection is more effectual than intracranial, which proves that the blood stream can convey it, and Nocard has shown that it is the solid rather than the liquid elements of dialyzed saliva which are infective. Whether it is the blood serum or the red corpuscles or the nerve fibers or all three which furnish the route from the periphery, I am unable to answer. No doubt in large quantities the blood serum conveys it. In the ordinary rabies of street infection experiments are at present, I think, tending toward investigations of the corpuscular route. That the organisms may escape after development in small numbers into blood and lymph channels to all parts of the body has been demonstrated by inoculation, although very rarely.

The clinical symptoms give us the key to the seat of development and later distribution, although the "Negri bodies," believed to be the cause of the disease, are not usually found most numerous at this seat. The chief symptom of extreme general hyperesthesia points to the sensory rather than to the motor roots, and the most intense hyperesthesia followed by paresis of the glosso-pharyngeal region would indicate greatest involvement of the nerve roots supplying that tract, namely, the glosso-pharyngeal, filaments of spinal accessory, pneumogastric, hypoglossal and gustatory branch of the fifth, all of which arise in the nuclei of the medulla and floor of the fourth ventricle.

Now comes the explanation of why the stage of the disease has even more to do with the infectiveness than position of the bites. The saliva only becomes infective after the micro-organisms have developed in the larger sensory and smaller motor roots and descended the nerve tracts to their terminations in mouth, pharynx and larynx.[3] The virus is, as before stated, quantitative rather than qualitative. As you know, the sympathetic nerves by their ganglia and fibers are most closely connected with the sensory; and in no part of the body are the sensory and ganglionic systems so intimately associated with each other as in the glosso-pharyngeal tract. Therefore, irritation of one irritates the other, and consequently in the earlier convulsive stage of the disease the salivary glands secrete a lesser amount of a thicker, not easily absorbed, saliva with no or very few germs. Later, when cerebrospinal centers are deluged and the germs are descending all three nerve tracts, paralysis comes on, the saliva becomes thin, copious and concentrated with virus, and never fails to infect. Fortunately for us the dog is then more apathetic than furious.

Hydrophobia is caused by inoculation with a specific microbe. To Negri[4] of the University of Pavia has been given, by many observers, the credit of discovering the probable cause of the disease. In 1903 he discovered bodies, present in the nervous system of animals, dead from rabies, which he believed to be protozoa. He described them as being rounded or oval in form, varying in size from 1 to 25 μ in diameter, staining distinctly with eosin and containing a central body surrounded by granules, these inner bodies being principally basophilic. They are more abundant and larger in the cells of Ammon's horn than elsewhere, but are often found in the Purkinje cells of the cerebellum, in the pyramidal cells of the cortex and in the cells of the pons, Gasserian ganglion, spinal ganglia and spinal cord.

Although there are many points in favor of the "Negri" bodies containing the cause of rabies, there are yet a few points to be cleared up; but if, as is quite generally conceded, their presence exists in no other disease, they are then a positive evidence of rabies and make it possible to diagnose the disease by the section method in a few hours and by the smear method in from one half to one hour from the time the animal arrives in the laboratory.

Frothingham's[5] method of rapid diagnosis by making impressions of the Ammon's horn upon a slide or cover glass gives excellent and rapid results. The method is as follows:

(1) "Dissect out the Ammon's horn and cutting with scissors at right angles to its length divide it into small disks as desired; (2) press a thoroughly cleaned slide upon a disk and remove it suddenly, or lifting the disk with forceps, press upon the slide. Four or more impressions may thus be made from one disk, depending upon its thickness. Four to eight impressions had better be made upon one slide, as some will naturally be better than others. Before the impressions have thoroughly dried, (3) place impression in methyl alcohol one-half minute or longer; (4) stain with Van Gieson's stain (heating gently) one-half a minute or longer; (5) wash in water, dry and examine."

Van Gieson's stain is made up as follows: Saturated alcoholic solution of fuchsin, three drops; aqueous solution of methylene blue, one drop; water 20 cc.

This saving of from two to four weeks over the biologic method is of vital importance in the treatment by the Pasteur vaccine.

ANATOMICAL CHANGES.

The anatomical changes of the disease are confined principally to the nervous system. The meninges are injected and edematous, and punctiform hemorrhages of brain and cord are found on section, due to degenerative changes of the walls of the veins and capillaries. The lower part of medulla oblongata shows these changes the most. The chromatin of the ganglion cells breaks up,

and processes disappear somewhat similar to appearance met with in tetanus, and there is a proliferation of the endothelium of the capsule of the ganglion cells. Salivary glands, mucous membrane of larynx and trachea are hyperemic and seat of petechial hemorrhages, as is also the stomach, which may be covered with yellow viscid mucus and contain coffee-ground débris but no food. Dogs' stomachs may contain all sorts of foreign substances if the convulsive stage of the disease was present.

SYMPTOMS IN CANINES.

The disease in dogs manifests itself somewhat as follows: In usually from three to seven weeks after infection the animal becomes restless and irritable, rarely fawning and affectionate, with marked hyperesthesia, starting and crouching in fear at the least noise. He shows a tendency at this stage to tear and swallow foreign bodies and a disposition for darkness and seclusion. The increasing brain infection now begins to cause marked signs of aberration of senses with hallucinations. He imagines he is being annoyed and injured and snaps viciously at phantoms or real objects. The furious stage, in which the animal runs wild and mad, now develops, and depending on the amount of infection and attenuation of the germ, gives way after a certain time to the paralytic stage, and ending in death in from four to seven days from beginning of disease.

On the amount of infective material and its attenuation, rather than on the dog, depends the relative prevalence of the convulsive or paralytic symptoms. In about one-third of the cases in dogs the disease is all convulsive. In the other two-thirds the paralytic element steadily increases, and in about 5% it is all paralytic in form, or what is known as "dumb rabies" or "drop jaw." These drop-jaw cases usually begin the epidemic. The animal wouldn't and couldn't bite in this form, but his saliva coming in contact with an abrasion might lead to the most horrible death known to man.

It is excellent judgment to beware of any dog that is sick until he is well or until a veterinary surgeon knows he has not rabies; especially, if he is gloomy, irritable and restless, if he snaps and barks at nothing, if he returns home from a disappearance looking dirty, exhausted and sick, if he seems more fond of you than usual and insists on licking your hands and face. Last, but not least, if he seems to have a foreign body in his throat, don't unguardedly look for it any more than you would look down gun-barrels for recreation. The body may prove to be the beginning paralysis of rabies. In rabific dogs their thirst is greater than their fear and they drink water early in the disease.

SYMPTOMS IN MAN.

The disease in man is more horrible to witness than it is possible to relate. There are usually three stages more or less well defined,—those of irritation, spasm and paralysis.

In the first, or melancholic, the scar of the original infection may become painful, itching and congested. There is depression, irritability, hyperesthesia, mental anxiety and insomnia or frightful dreams. There is thirst and yet such intensely painful spasms of throat and chest on attempting to drink as to threaten suffocation and cause indescribable fear at the sight or sound of water.

In twelve to twenty-four hours the spasmodic stage is well developed, and the laryngeal symptoms are frightfully increased, with intense dyspnea and pitiable struggling and gasping. The patient froths at the mouth and expels unswallowed saliva in all directions, while his congested eyes and face and agonized expression show plainly the anguish of his sufferings. With the increasing hyperesthesia, the slightest impression on the senses, such as light, currents of air from moving bed covers or brushing away flies, or the odors of chloroform or ether used to control the symptoms, cause the paroxysms to return when the patient, in a fit of mania, may viciously attack anybody near.

The intervals between the paroxysms gradually shorten until exhaustion seems to modulate the stage into paralysis, unless death supervenes from apoplexy or asphyxia. During this apparent stage of exhaustion, which is due to the ever-increasing brain infection, the patient seems to be much easier, mind is clear and deglutition may be possible, but beginning analgesia, dropping of the jaw, salivation and rattling in the larynx steadily increase, and coma and death enp all in from one to three days from beginning of symptoms. As with canine madness, the paroxysmal stage may be short or absent, as may also the paralytic stage, when it has been mistaken for tetanus, just as the so-called "spontaneous hydrophobia" was no doubt sometimes tetanus, as was suggested by Dr. James Mease[6] of Philadelphia in a prize essay on "Rabies" in 1793.

Not so long ago a coroner in Philadelphia refused to receive certificates signed hydrophobia and returned them "for correction." A diagnostician with such views should be excluded before hydrophobia is excluded in differentiating between the few functional and organic nervous diseases, such as hysteria, epilepsy, strychnine poisoning, tetanus, and acute ascending spinal paralysis for which it has been mistaken. The diagnosis will then be easy, except perhaps in early deaths, when autopsy might be the only positive proof.

Time and care will point out hysteria or what is known as lyssophobia.

PROGNOSIS.

There have been recoveries reported by good authorities in both dog and man without treatment, but recoveries in man are if authentic exceedingly rare. Those cases probably received the minimum amount of virus with the minimum attenuation possible to produce the disease, and possessed at the time not only a high opsonic index, but also a strong and willful nervous system. It has been variously estimated that hydrophobia develops in from 5% to 50% of all persons bitten by rabid animals and untreated by vaccine. Sta-

tistics would indicate 10% to 15% to be a fair estimate.

Unfortunately there is about as much ignorance and prejudice regarding the Pasteur vaccine treatment as there is regarding the disease itself, both within and without our profession. I heard recently one of our most eminent surgeons of this state in an address before a body of laymen give his personal opinion as against the use of it. The Pasteur preventive treatment is based on the theory of the production of an active immunity depending either on an antitoxin or on a germicidal state of the tissues, probably the latter. It has no effect, beneficial at least, if the symptoms of the disease have appeared.

The vaccine is prepared from the spinal cord of a rabbit killed by inoculation with "fixed virus." Parts of this cord are dried anywhere from three to fourteen days. That part dried three days contains practically all of the toxic potency. That part dried fourteen days loses all its toxic potency. One centimeter in length of cord dried fourteen days is rubbed into an emulsion with 5 cc. of sterile broth or salt solution, and 3 cc. of this fluid are used for first injection. Twenty of these injections now follow each other within a period of fifteen days, in which the spinal cord for each successive injection is usually subjected to a shorter drying period, so that on the fourteenth and fifteenth days a cord is used which has been dried only three days.

What is known as the "intensive treatment," in which twenty-four injections in fifteen days, with six more on the six next days, is used for those cases bitten about the head and neck, and for the cases not seen for several days after inoculation. Our intensive treatment is used in Berlin as their ordinary treatment, and in other cities there are minor differences. We get our vaccine for use in Massachusetts from the New York Board of Health, bottles of proper amount and strength coming each morning by mail at a cost of $25 for each course of treatment. The Boston City Hospital has procured it in this way for nine cases treated by them since last June.

What are the results of this treatment, which, since its origin by Pasteur, has been so actively opposed, some even claiming that the percentage of cases which developed rabies had been increased since its beginning? At least 10% of all persons bitten by rabid animals, before or without the use of Pasteur vaccine, developed the disease and died. Of all persons bitten by rabid animals, with subsequent Pasteur treatment, less than 1% have died. The mortality has never reached 1% in Paris since the institute was opened, while in the New York institute it has only twice exceeded 1%. Dr. Keirle,[7] Director of Pasteur Institute in Baltimore, writes me that he has treated 998 cases with one death.*

These statistics answer all questions as to its efficiency, and justify the honor paid recently to Pasteur when he was elected by the citizens as the most popular man in France.

* Dr. Keirle has since reported 1,000 cases treated, with two deaths, one of which may have been due to chronic Bright's disease, which was present before and during treatment.

"Typical serum," which will protect animals in doses equivalent to 1-25,000 of body weight is now prepared by inoculation of sheep with rabic material attenuated by digestion according to the Italian method. It may be dried and kept indefinitely, and should be used in hydrophobia instead of the Pasteur vaccine, if the symptoms of the disease have already appeared. Although harmless, its curative efficiency has not yet been satisfactorily tested on the disease in man. It has been used with favorable results on animals. Cauterization, after the inoculation by the rabid animal of much of the thin saliva, of the beginning paralytic stage would probably no more control the action of the germ than cauterizing a hypodermic of nitroglycerin would control the action of that drug. It is one of the things to be tried, however, and if used early might prevent the absorption of sufficient quantity of the thick viscid saliva of the convulsive stage necessary to cause the disease. Pure nitric acid has experimentally given the best results and should be used freely.

But that there are any cases of hydrophobia in this country is a reflection upon our ability in the department of sanitary science. It is within our power to absolutely exterminate rabies, and we can do it, or we can allow rabific dogs to viciously lacerate and kill by the most horrible death known, hundreds of children annually, for whom we are responsible, as well as thousands of dogs for whom we are also responsible. Ten thousand dogs alone died of this disease in France between 1900 and 1904; and I wish now to close this paper by calling your attention to the rational prophylactic treatment, by enactment and enforcement of laws, such as exist in Great Britain, Germany, Sweden, Norway, Switzerland and other places.

Australia shows perfect results of a law requiring all dogs imported to be quarantined for six months. No case of rabies has ever appeared on this island. Great Britain at home has achieved brilliant results after hundreds of subjects have died from the disease. From 1887 to 1898, inclusive, there were 147 deaths from hydrophobia in man, and 2,554 in dogs. During this period dog laws were sometimes in force and other times rescinded. Strict laws regarding muzzling and quarantine have since then been continually in force, and in 1900 no deaths from hydrophobia occurred, the first time in more than fifty years, while during 1900, 1901 and 1902 only twenty cases of rabies in dogs developed. Since the end of 1902 there have been no cases, and the disease, which between 1848 and 1898 caused the deaths of more than 1,000 persons, has been by the application of a few simple laws exterminated in Great Britain.

Germany saw the necessity and justice of dog regulation many years earlier, and wisely and promptly acted, thus ending the ruthless sacrifice of human life through misdirected sympathy. Between 1848 and 1853 Berlin averaged 35 cases of rabies annually. During the spring of 1853 a marked increase in the number of cases resulted, on July 20, in an order to muzzle all dogs. Four cases developed the next year, one in 1855, and none for the next seven years. According

to Dr. Salmon,[8] in his year book, Department of Agriculture, 1900, no case had occurred in Berlin since 1883. The same report states that in Sweden previous to 1870 there were 8 or 10 deaths annually from hydrophobia. Laws were then enacted and enforced, and there have been no deaths since.

Literature on the disease in the United States would not indicate that its seriousness or frequency has been properly appreciated by the medical profession. For the year ending May 31, 1890, there were found among incomplete records 143 deaths from hydrophobia in the United States. Twenty-one died here in Massachusetts and 16 in Georgia. Incomplete records of 73 cities between 1890 and 1899, including in some cases the first half of 1900, show 230 human deaths after eliminating doubtful ones.

In Massachusetts, between 1857 and 1880, I have found records of 54 deaths and during the last 20 years there have been at least 60 more with many exposed cases under observation and treatment at present. At least 100 persons have been bitten by rabid animals in Massachusetts during the past year. At a later date I shall be able to present to you more complete data on the prevalence of the disease in this country.

It is true that the layman would need a good deal more information on the subject to support legislation for the eradication of the disease, just as it has been necessary to educate them regarding the infectiousness and rational treatment of tuberculosis. It is a duty incumbent upon us to furnish them with such knowledge that they may assist us in obtaining proper laws for its eradication, and it is upon us, who have in the past secured the many sanitary laws for the public welfare, that the duty devolves of actively guiding into existence such national and state laws as the following: *

1. Control of the disease in the United States to be placed under the supervision of the Chief of the Bureau of Animal Industry at Washington, as are other epizoötic diseases, such as foot-and-mouth disease, according to the Act of Congress of May 29, 1884.

2. Full authority vested in the state cattle or other appointed commission to act as may be necessary for the eradication of the disease, in conjunction with the United States Bureau of Animal Industry at Washington, whenever rabies appears in the state.

3. All licensed dogs to wear collars and metal plate of special form, that they may be readily recognized.

4. Prompt capture of all dogs not properly tagged, with subsequent humane destruction, unless properly licensed within a short time.

5. Efficient muzzling of all dogs unrestrained in public places for a period of at least one year.

6. Dogs imported from countries other than those from which rabies is excluded to be quarantined for six months.

As Massachusetts is not isolated, and our dogs at the borders of the state are often infected by or infect dogs in contiguous states, interstate regulation under the supervision of the chief of the Bureau of Animal Industry at Washington seems to me to be the only efficient method of eradicating the disease in this and other states.

In Berlin its eradication was made effectual by conjoined action on the part of Prussia, and in Great Britain by like action of England, Scotland and Wales.

Dr. Peters [9] in his excellent address on "Rabies" before the Massachusetts Board of Health at a recent meeting quotes Dr. Cope, Chief Veterinary Officer of British Board of Agriculture, as saying: "It may truly be said that the board has never undertaken a duty which has rendered so great a service to the community of this country from the point of view of human health as the extinction of rabies in the dogs." Dr. Cope died recently. The protection he gave to man and dog against rabies can never die. Let us furnish our citizens that same protection. Let us answer now that question that was asked fifty years ago and promise those that trust us as their sanitary guardians that both human and canine life shall be protected by the ægis of the law.

* Since this paper was read, these six suggestions for legislation were presented in the form of resolutions at the fifty-eighth session of the American Medical Association at Atlantic City, through the courtesy of Dr. Richard C. Cabot, delegate from Massachusetts. They were favorably acted upon by the House of Delegates and are now in the hands of the Legislative Committee, which will do what it can to carry out the declared wishes of the American Medical Association in national and state legislation.

THE UTERO-SACRAL LIGAMENTS.*

BY DANIEL H. CRAIG, M.D., BOSTON,

Surgeon to Out-Patients, Free Hospital for Women, etc.

IN accepting your kind invitation, so graciously extended to me through Dr. Greenwood, to talk to you this evening, I was influenced to utilize this theme by two considerations: first, the decided importance of the subject itself; and second, by the surprising and very gratifying interest

* Read by invitation before the Waltham Clinical Club.

manifested when I demonstrated the technique of their shortening in a case of retroversion at the Free Hospital for Women last June, before members of the American Medical Association during its Boston session. I am, perhaps, still further influenced by the fact that all definite knowledge of these ligaments seems to be very strictly confined to the gynecologists, and by no means all of these latter appreciate them at their full significance. For example, to show the position not only of the general practitioner, but also of others, not a great while ago one of Boston's leading surgeons of the younger generation referred a patient to my Out-Patient Clinic at the Free Hospital for Women and I returned her with a diagnosis of chronic inflammatory thickening and shortening of the utero-sacral ligaments and advised, in connection with other operative treatment, their section. The patient was promptly returned to me, with the request to operate and a frank avowal that he knew nothing about operations on these ligaments.

Their anatomy is either misunderstood or not understood at all. I have found by repeated conversations that most physicians regard the utero-sacral ligaments as very vague, inconsequent, peritoneal folds, which they have never seen outside of text-books, and possibly the dissecting-room, and have never felt. The first portion of this postulate is entirely wrong. They are very definite, not peritoneal, and very efficient under proper circumstances. While Bovée has gone very elaborately into their complete and minute description for general purposes of usefulness, I prefer Deaver's description, which is as follows: "The utero-sacral ligaments are flat, muscular bands, which extend from the uterus at the level of the internal os, beneath the layers of the recto-uterine ligaments, to the sides of the sacrum, opposite the lower borders of the sacro-iliac articulation. In the first part of their course they are in relation with the lateral walls of the pouch of Douglas, and finally run on either side of the rectum, near the junction of the sigmoid flexure and the upper portion of the rectum."

In this description he very properly emphasizes the distinction between the true muscular utero-sacral ligaments and the false peritoneal portion, which he describes as the above-mentioned recto-uterine ligaments in the following words: "The false posterior or recto-uterine ligaments are composed of peritoneum, are two single serous layers which pass backward from the posterior surface of the uterus and vagina to the upper portion of the rectum, where they are continuous with the peritoneal coat of the rectum. These folds of peritoneum form the lateral boundaries of the pouch of Douglas. External to each of these false ligaments are found the true, or muscular, utero-sacral ligaments, extra-peritoneal connective tissue and anastomosing branches of the uterine and hemorrhoidal vessels."

Deaver's language is too plain to leave any doubt as to the actual muscular structure of these ligaments and physiology has taught us that muscular tissue is not furnished anywhere throughout our bodies, without definite purpose and definite actions.

I believe that I am doing you no injustice when I express the belief that very few of you have ever considered the true utero-sacral ligaments as an entity apart from the very unimpressive peritoneal folds, which become visible from above when the uterus and rectum are widely separated. Realizing their muscular structure necessarily modifies our entire conception of their physiology.

Furthermore, the opinions of Testut, in France, and of Nagel, in Germany, fully confirm and even emphasize the correctness of Deaver's and Bovée's descriptions.

In the light of this anatomy and recent gynecologic surgery the physiology of these ligaments has become definitely known and indubitable. They certainly play an important rôle, not only in the support of the uterus, but also in the maintenance of its proper axis. As this latter point will come up later we will consider it at that time.

The pathology of these structures, considered individually, is changed from that of the peritoneum to that of muscular tissue, but since, as a matter of fact, the line should not, arbitrarily, be so strictly drawn between the true and the false as is done anatomically, we have a mixed pathology in practically all inflammatory lesions of these structures, and I shall endeavor to convince you later that at least one condition which has for years been considered pathological is in reality but a fine example of the physiology of the muscles comprising these ligaments.

The pathology should be divided into the congenital and the acquired. They are relatively frequently the subject of developmental arrest, and I am unable to say whether the arrest is prenatal or post-natal, — whether in a given case the original norm never obtained, or whether at birth the anatomy was normal but an arrest occurred at the pubital development of the other allied structures. The developmental lesion which is most commonly met and of the greatest practical importance is an improper insertion into the uterus, being attached to the uterus above or below the level of its normal attachment.

The acquired forms of pathology almost invariably originate in inflammatory processes reaching the ligaments by extension from contiguous structures, which structures may normally belong in contiguity with the ligaments, or which may have become adjacent to them only by antecedent pathological displacement, as for instance in the case of a prolapsed ovary or tube.

The principal gross manifestations of such inflammation are tumefaction and rigid muscular contraction, the tumefaction being due in part to edema and in part to the thickening consequent upon the muscular foreshortening.

To proceed from generalizations to more specific consideration of individual lesions, let us first consider contraction.

CONTRACTION OF THE UTERO-SACRAL LIGAMENTS.

(*a*) *Inflammatory contraction* is well understood and has been repeatedly described by vari-

ous observers. It is due to an extension of contiguous inflammation usually from an inflamed ovary, which, through its tumefaction and consequent increased weight, has prolapsed and so come into close apposition with the ligament. And there is a very intimate relationship between a prolapsed ovary and the utero-sacral ligament of the same side. The most immutable attachment of the ovary is by its ligamentum proprium to the cornu of the uterus, and in the downward course of the prolapsing ovary this ligament must form the radius of the arc through which it descends, and the length of this ligament is such that, the uterus remaining in anything like a normal position, the ovary will impinge upon and often rest upon the outer aspect of the recto-uterine fold and its subjacent utero-sacral ligament. If then the ovary be inflamed, or later become inflamed, the recto-uterine fold becomes the seat of a localized peritonitis, in which commonly the subjacent connective tissue and the true ligament become involved. This localized peritonitis, of course, results in an adherent ovary. Should the uterus be more or less retroverted, the approximation of the fundus to the sacrum permits the ovary to fall deeper into the pelvis, and it thus reaches the cul-de-sac of Douglas and rests upon the median aspect of the recto-uterine fold instead of the outer aspect as above, but the advance of the process is in no way affected.

The same sequence of events is also possible in those forms of sacro-salpinx in which, through adhesive inflammation, a collection of fluid, either pus, blood or serum, becomes saculated in or near the fimbriated end of the tube. The proximal portion of the tube forms the radius of the arc in this instance. Moreover, digital differentiation of these two lesions, per vaginam, I have always found impossible, unless the other organ could be distinguished in another location. Of course the two very commonly co-exist.

In cases in which the inflammatory processes in tube or ovary are still active, the contraction of the utero-sacral ligaments can merely be considered as a complication and no special individualized treatment can be administered, and coincident treatment seems advisable only when it is felt that the inflammatory disorganization has reached such a degree that spontaneous resolution cannot take place on the removal of its cause.

A cause of contraction which, so far as I know, has never been mentioned by any one until I last month submitted a paper entitled, " Contraction and Shortening of the Utero-Sacral Ligaments. A Suggestion as to Etiology and Treatment," is what I like to term:

(*b*) *Defensive contraction.* — In this paper I explained at length the nature of this form of contraction to which I wish to refer briefly here. This form of contraction came to my attention in perfecting a treatment for chronic endotrachelitis and depends entirely upon a correct realization of the relatively strong muscular structure of these ligaments. By the contraction of their muscular fibers the cervix, and to a lesser extent the lower portion of the uterus, is strongly drawn backward and upward into the hollow of the sacrum and immobilized. I have many times observed this position of the uterus, commonly referred to in the text-books as retrocession, retroposition, in my observation of cases of endotrachelitis, and finally began to realize that the uterus returned to a normal position, owing to a relaxation of these ligaments very promptly after the cure of the endotrachelitis. In other words, the ligaments, although much shortened and thickened, rigid, readily palpable and very sensitive, were in reality never the seat of a true inflammation at all, but were merely contracted, following the natural law of immobilization in the defense of an inflamed cervix.

Relaxation. — This is a subject regarding the etiology and pathology of which I am able to learn practically nothing either by observation of the great number of cases seen or by reading. We all realize that it is an important factor in every case of retroversion and retroflexion and prolapse, but know practically nothing of its antecedents. I say in retroversion and retroflexion, because it is largely the degree of relaxation of these ligaments which determines the difference. When the ligaments are freely relaxed retroversion results, but when this relaxation is slight or absent, the fundus may be forced backward, but the cervix cannot move forward and so the uterus becomes flexed.

One fact regarding this relaxation is important, and that is that in cases of retroversion known to be of very long standing and of extreme degree I have never yet failed to find them sufficiently firm and of sufficient caliber to permit of their comparatively easy manipulation. This is a fact which I think many who have not had personal experience in their operative manipulation have failed to realize. Everyone seems to regard these ligaments as an operative bugaboo.

The diagnosis of lesions of these ligaments is usually very easy. The only difficulty is encountered in the purely inflammatory cases, in which the prolapsed tube or ovary and the recto-uterine fold as well as the utero-sacral ligaments are all inextricably coalesced into a tender mass behind and beside the cervix, but fortunately it is only in those exceptional cases in which the ligaments require coincident section while operating for the more serious and primary condition that such differentiation is necessary, and it can thus be made most advantageously after the obscuring adhesions have been broken up and the ligament so exposed as to be amenable to inspection, as well as direct palpation.

In those cases of inflammatory contraction, in which the original causative inflammation has resolved, leaving the chronic condition in the ligaments and in those in which the causative lesion does not mask the true condition of the ligaments, the diagnosis is relatively easy. The first thing which attracts attention is the retraction of the cervix far back into the hollow of the sacrum and to a variable extent upward. The first impression is as to the lessened accessibility of the cervix. Generally deep insertion of the examining finger with strong upward forcing

of the perineum is required to reach to the full depth of the posterior vaginal fornix, while at the same time the uterus is being forced downward by the external hand over the hypogastrium. Having reached the apex of the posterior fornix, pressure made upward and forward with the tip of the finger, in such a way as to draw the cervix out from the sacrum, will be found to cause an altogether unusual degree of pain; while at the same time, if the tip of the finger is carried outward about one-half inch from the median line, a cord-like structure will be felt, which is very firm, very tender and in diameter may vary from one-eighth to one-half inch or even larger. Its antero-posterior linear feel as well as its characteristic resilience instantly distinguish it from prolapsed appendages, neoplasms or fecal masses in the rectum or sigmoid.

The pain spoken of above upon drawing the retrocessed uterus away from the sacrum deserved fuller mention. The finger-tip should be placed against the posterior aspect of the cervix so low down that in the manipulation no pressure can be made directly upon the suspected ligament, and by the flexion of the finger the cervix drawn sharply forward. If the ligament is diseased this traction causes intolerable pain and the patient will involuntarily exclaim and raise the entire hips off the examining table in her efforts to lessen the tension on the ligaments. On the other hand, such traction is either inoffensive or only mildly painful in adnexal lesions.

Furthermore, inasmuch as it is no more possible to distinguish the normal utero-sacral ligaments than it is the normal broad ligaments, the mere fact of being able to distinguish them on palpation is evidence of some pathological condition.

One further lesion is seldom recognized and is yet easy of diagnosis. This is the too high insertion of these ligaments with the resultant retroversion. The axis of rotation of the uterus in its antero-posterior versions is very nearly at the level of the internal os, but in reality a little above it at the point of insertion of the strong musculo-fibrous base of the broad ligament, which the Germans so wisely designate the " cardinal ligaments of the uterus." Normally the utero-sacral ligaments are inserted below this axial point, keeping the cervix behind the axial point and hence the fundus anterior to this point, or in what is commonly characteristized as normal anteversion. The contraction of the utero-sacral ligaments draws the cervix backward at the same time that the round ligaments draw the fundus forward after the fundus has been displaced backward; as, for example, by distention of the bladder. In those cases, therefore, in which, through arrest of development, faulty development or faulty growth, their attachment is above the axial point, they as inevitably produce retroversion by drawing the body instead of the cervix backward. Usually in such cases the anterior vaginal and vesical attachments with the utero-vesical folds are correspondingly low, still further tending to a forward position of the cervix,with the consequent retroversion of the fundus.

This combination of abnormalities is surprisingly easily recognized and equally surprisingly seldom recognized. This is the one class of movable retroversions which can never be cured by Alexander's operation alone, and which through improper attempts to do so has brought that operation into an undeserved disrepute, just as its improper employment in adherent or otherwise complicated cases of retroversion has.

The recognition of this form of retroversion depends upon the realization of an abnormally deep posterior vaginal fornix, with usually a very high attachment of the vagina to the uterus posteriorly, together with a very short anterior portio vaginalis reaching in some extreme cases almost to an entire absence of any anterior lip to the cervix, the vaginal wall seeming to start from the very border of the os externum. On replacing the uterus it is much easier to distinguish these characteristics, and unless there are or have been inflammatory complications resulting in adhesions, such replacement is easily effected bimanually, but the uterus will return promptly to its abnormal position. As would be expected, pessaries are not well tolerated. This form of retroversion is spoken of as " congenital retroversion."

The diagnosis of defensive as distinguished from inflammatory contraction depends upon the realization that it is only a symptom of some more serious condition, most commonly endotrachelitis, and especially upon the recognition of this original lesion, of which it is a symptom, and finally upon the exclusion of the inflammatory form of contraction through the lack of evidence of past or present contiguous inflammation.

The treatment may be palliative or operative, according to the individual case. In those cases in which an inflammatory contraction is consequential to a mild inflammatory condition in the appendages, which is itself amenable to non-operative measures, the complicating contraction will often, if not of too long duration, yield *pari passu* with the adnexal lesion. In such cases no special treatment need be instituted until the adnexal lesion has been cured, since the packings with or without medication, which best serve to cure the adnexal conditions, also relieve the ligaments. After-treatment is no longer needed by the original condition if, as often happens, a certain degree of contraction persists. I have seen most benefit from a dressing which I call an ichthyol T. A firm roll of non-absorbent cotton two inches long and one inch in diameter is thoroughly smeared with a mixture of ichthyol and glycerin and placed transversely behind the cervix in the posterior vaginal fornix and sustained in this position by a similar roll, about four inches long, which vertically fills the vagina down to the bulbo-cavernosus muscles. Threads are attached to each roll, so that they may be removed by the patient after about seventy-two hours.

The treatment of defensive contraction, since it is itself a symptom, resolves itself into the removal of the disease, of which it is a symptom. In the vast majority of cases, then, our problem is

the cure of an endotrachelitis, and I have found no treatment so prompt and permanently efficacious as the little operation with the specially designed instruments which I described last year.

The operative treatment of contraction of the utero-sacral ligaments is confined to a very small number of cases of such long standing that all manner of palliative treatment must fail, as the ligaments have become so infiltrated by fibrous tissue that relaxation is a physical impossibility. It rarely occurs in such cases that operation should be undertaken for their relief alone. Usually grave and long-standing antecedent or complicating lesions demand operative intervention, in which case the simple cutting of the ligaments either from above, during a celiotomy, or from below in a vaginal section, is very simple. In those infrequent cases in which their section is indicated, a simple vaginal cutting through an ample transverse vaginal incision is very easy, without invading the peritoneal cavity at all. It must be borne in mind that in this class of cases the ligaments are much larger than normal and hence more obvious and more easily manipulated. The cervix should be kept well forward for two or three days following the section of the ligaments. The opening of the abdomen for the section of these ligaments is entirely unnecessary, and for this alone seems to me unjustifiable.

The above small class of cases represents the easiest possible operations upon the ligaments.

In relaxation of these ligaments I am skeptical of any form of palliative treatment accomplishing anything except in very recent cases. In such recent cases my method of palliative treatment is by means of a systematic packing of the vagina so as to sustain the replaced uterus in its normal axis and at the same time avoid all tension upon the ligaments. Thus pessaries I do not use in these cases for mechanical reasons. The pessary sustains the uterus in normal anteversion by so forcing upward and backward the vaginal wall that, through its attachment, the cervix is thus drawn backward and, of course, the fundus thrown forward. But in order to accomplish this the transverse bar of the pessary must push a roomy vagina so far upward that the utero-sacral ligaments are stretched over this bar and hence have no opportunity for resolution to their normal length and strength. On the other hand, with the packing installed as I have elsewhere described, the cervix is held properly back, and yet the posterior vaginal fornix is empty and the ligaments have all possible chance of recovery of their normal tone. To briefly repeat this method of packing, it is as follows: One of the wool segments of the "kite-tail" dressing is placed in each lateral fornix and one in front of the cervix, and then the vagina is systematically packed down to the level of the bulbo-cavernosus muscles, where the last layer is disposed as a transverse bridge, thus leaving the bladder and rectum free and the perineum free from the downward pressure of the dressing.

Massage, other than that passively performed by such a packing, has not proved satisfactory in my experience.

The operative shortening of these ligaments is intermediate in difficulty between their easy section and their difficult transplantation when faultily inserted. The difficulty lies in their softness and attenuated diameter, while these difficulties are compensated by the free mobility of the cervix. Here, as in shortening, it cannot be too emphatically stated that no justification exists for the opening of the abdomen for any operation involving these ligaments alone, while it is equally true that all these operations can be done from above when the abdomen is already open for other reasons.

In order to shorten these ligaments a free transverse incision is necessary at the cervico-vaginal junction. Through this incision, after working upward through the loose connective tissue between the uterus and the rectum, the ligaments are very readily detected by the finger, especially if they are intermittently tightened by traction upon the cervix. They are then transfixed by a tenaculum and readily drawn into sight. Some operators advise resection of a piece of the requisite length and approximation of the distal segment to the uterus by suture. This I do not like, but prefer to transfix the ligament at the proper point to give the requisite shortening with a suture, and then with the same suture take up a firm hold on the cervix just below the normal insertion. Before tying the first suture, similarly place the second in the opposite ligament, thus saving the advantage of the free mobility of the cervix. Finally, tie both sutures. By this technique three things are accomplished. If the sutures fail of their purpose the patient is at least no worse off than originally, which may not be true if the ligaments were cut. The folded ligament forms adhesions and becomes stronger than originally, and lastly the attachment being slightly below the normal attachment gives them a little greater leverage in drawing the cervix backward.

In transplanting the faultily inserted ligaments the same technique is followed up to the point of inserting the sutures. It is very seldom that the ligaments are so short as to need cutting at their uterine insertion in order to get sufficient length to reach to the new attachment. I have never seen such a case. The ligaments being as freely as possible exposed, which is much less than in the preceding class of cases, because of the less mobility of the cervix, estimate the distance between the point of faulty insertion upon the back of the uterus and the lowest point to which they can be sutured and transfix them with the suture at this distance from their uterine ends. Pass the sutures deeply into the cervical tissues at the elected point for the new attachment, and finally tie after both sutures have been placed.

In addition to the above transplantation some form of plastic work is almost always necessary in these congenital retroversions, such as making a deep transverse incision and closing it vertically, thus shifting the cervico-uterine attachments upward. Shortening of the round ligaments by one

technique or another is often a wise or necessary coincidental treatment.

In the close watching of these congenital retroversions after operating as above, some very interesting anatomical data have been observed. We have all heard of the strong influence exerted by the strong pelvic facia in determining the normal axis of the uterus. That is, the uterus has been spoken of as pushed down through these fasciæ at a certain angle, which their attachment tends to perpetuate. These cases illustrate that point beautifully. The cervix was originally " pushed down through " at a wrong angle. On examining these cases six weeks to two months after operation I have invariably found the fundus forward; but the cervix still showing a decided tendency to a forward position, in many cases almost a true anteflexion and without any treatment, in five or six months the cervix comes down to its normal relation to the body in every case.

THE CONTAMINATION OF THE AIR OF OUR CITIES WITH SULPHUR DIOXID, THE CAUSE OF RESPIRATORY DISEASE.

BY THEODORE W. SCHAEFER, M.D.,
Formerly Professor of Chemistry, University Medical College, Kansas City Veterinary College, etc., Kansas City, Mo.

THE importance of sulphur dioxid as an impurity of the air of our cities and its injurious effects upon the organs of respiration is a subject that has not received the attention in works on hygiene which it demands. Most of the works on hygiene give us but a very meager information or none at all of sulphur dioxid as an impurity of the atmosphere. They chiefly mention and describe its antiseptic and disinfectant properties. The writer has been studying the noxious effects of sulphur dioxid as an impurity of the atmosphere for the past ten years and he had arrived at the conclusion that it is one of the most potent causal factors of asthma. Some of his observations were published elsewhere in 1902. It is only within the most recent years, especially through the investigations of Kionka,[1] that the importance of the toxic properties of sulphur dioxid in the form of sulphites has been made apparent and established.

The atmosphere, being a mixture of gases, gives, according to the most recent investigations, the following average composition in one hundred volumes:

Oxygen	20.60	volumes.
Nitrogen	76.90	"
Argon	1.00	"
Carbon dioxid	0.04	"
Aqueous vapor (about)	1.46	"
Ozone, hydrogen dioxid Nitrogen acids Marsh gas Sulphur dioxid (in towns and volcanic districts) Hydrogen sulphid	traces.	

Besides the three above-mentioned elements there are in the air hydrogen gas (according to Gautier 0.015%), neon, krypton, xenon, helium and coronium, which have only a scientific interest. According to Mendeléeff's " Periodic Law " a number of other elements are believed to exist in the atmosphere, but remain to be discovered by the chemist in the near future. Dust, being a normal constituent, is found in the air at all times.

PRESENCE OF SULPHUR DIOXID IN SMOKE AND FOG.

Since the air is the great receptacle for all gaseous emanations, other substances, in the vapor or solid form, may be discovered in it by chemical and microscopical means. Sulphurous anhydrid or sulphur dioxid, for instance, can often be traced in it, being derived from domestic, manufacturing or tellural sources. In the combustion of coal, which contains iron pyrites (FeS_2), and coal gas, which contains hydrogen sulphid and other gaseous sulphids, the sulphur is oxidized and converted into sulphur dioxid, which passes into the air in which it is rapidly diffused. The air of every large city, especially in the manufacturing districts, becomes polluted with free sulphur dioxid in variable proportions. To form even an approximate idea of the enormous quantity of waste matter poured into the air of a city like London, it is worth while mentioning the statement quoted by Egbert,[2] that " It has been calculated that for every ton of coal burnt in London something like three tons of carbon dioxid are produced," and as the city's coal consumption is over 30,000 tons per diem, we can see that its atmosphere must receive the enormous daily contamination of about 300 tons of soot and 90,000 tons of carbonic acid. From this calculation the writer has made another proportionate calculation from which he finds that at least 2,700 tons of sulphur dioxid are produced at the same time, helping to augment the further daily pollution of the atmosphere of that city.

Sulphur dioxid, after uniting with the oxygen and aqueous vapor of the air, is converted into sulphuric acid.

A portion of the sulphuric acid, says Thorpe,[3] is probably derived from the oxidation of the iron pyrites, which is generally present in coal to the amount of 3%, although some coals contain much larger quantities of this substance. The amount of sulphur which it contains has an important bearing on the value of the fuel in nearly all its applications. When coal is burnt the sulphur escapes as sulphur dioxid. This gas exerts a very detrimental action on vegetation, and by its proneness to pass into the state of sulphuric acid in the atmosphere it brings about the rapid deterioration of the stone-work on which it may be precipitated. It has been calculated that as much as 20 tons of oil of vitriol (sulphuric acid), produced by the combustion of coal, are annually brought down by the rain in a large city like Glasgow or Manchester.

Dr. R. Angus Smith[4] has shown that in large towns the amount of sulphates is largely increased, owing to the combustion of coal which contains iron pyrites. The nature of the sub-

stances present in the rain has also been investigated by this indefatigable worker in air analysis, who has shown that the examination of rain water affords a method of determining the impurities in air, and hence probably its comparative sanitary value. He has made a number of interesting analyses to show the general character of the rain (and therefore of the impurities of the atmosphere) in various parts of Great Britain. Thus the results of the average number of determinations gave for the rain of London 3.87 parts of sulphuric acid in a million (?), for Liverpool, 11.56 parts in a million, Manchester, 10.17 parts in a million, and Glasgow 15.13 parts in a million. He further states that the rain water in large towns is not infrequently acid, owing to the presence of sulphuric acid. When rain contains 40 parts per million of free acid, the vegetation of the district is rapidly affected. Thorpe says that the sulphur compounds in coal gas are a source of much annoyance. When burnt they give rise to acid products which rapidly corrode metal fittings, decorations, tapestry, painted woodwork, paper, gildings of books, etc.

VARIABLE PROPORTION OF SO_2 IN THE ATMOSPHERE OF CITIES.

The proportion of carbon dioxid is an index of the amount of sulphur dioxid in the atmosphere. When the amount of carbon dioxid is increased the proportion of sulphur dioxid is correspondingly augmented in the air of cities and manufacturing districts. Every ton of coal in burning yields its proportionate volume of carbon dioxid and sulphur dioxid, for every sample of coal contains a certain percentage of sulphur in the form of iron pyrites. The proportion of SO_2 in the atmosphere of cities is not constant throughout the year. There is more SO_2 in the air in winter than in summer. There is an excess during heavy fogs, attaining, at times, almost the CO_2 equivalent of the atmosphere. As the amount of carbon dioxid varies in the cities, so also does the quantity of sulphur dioxid vary. *Pari passu*, during the night the sulphur dioxid increases in exact ratio with the progressive increase of carbon dioxid. During the prevalence of thick fogs, the air being in a stagnant condition, the sulphur dioxid equivalent is correspondingly increased with the carbon dioxid content. As much as 8 or 9 volumes of carbon dioxid in 10,000 volumes of air having been noticed on a foggy day, we infer from this likewise a proportionate increase of sulphur dioxid, there being, however, no recent exact quantitative data of sulphur dioxid determinations in the atmosphere at hand.

Bloxam[5] says that when damp air is chilled the water is deposited from it in the form of fog unless the air be optically pure, when no condensation of water occurs. It would appear from this that the dust particles in the air form nuclei around which the aqueous vapor can precipitate, much as crystals form around a particle in a supersaturated solution. The aggravation of a fog by smoke may perhaps be partly due to such a cause. It has been shown that the dust particles are not alone in causing precipitation of aqueous vapor, many gases which are free from suspended particles having a similar effect. Sulphur dioxid is an example; this gas is always present in London air, being a product of the combustion of coal containing iron pyrites; it is more abundant in foggy weather, but whether it is a cause of the fog or is merely retained by it remains uncertain.

The writer, however, believes that sulphur dioxid, being a very heavy gas, with the specific gravity of 2.25, is alone capable of creating a fog, as is at once shown when it is brought in contact with the atmosphere, from which it absorbs aqueous vapor, causing dense, heavy fumes. The dust or carbon particles, coming in contact with this acid vapor, enhance its gravity materially. Fog usually collects in the lower portions of a city, especially in depressed localities known as "hollows," where it remains until dispersed by air currents. The reason for all this is explained by the physical properties of heavy gases. Fog also contains an excess of carbon dioxid, having a specific gravity of 1.524; it being consequently one-half heavier than atmospheric air. Fog also contains an excess of sulphur dioxid, having the specific gravity of 2.25; the latter gas is, therefore, two and a quarter times heavier than air.

DELETERIOUS EFFECTS OF SULPHUR DIOXID UPON THE RESPIRATORY ORGANS.

It is a well-recognized fact, says Harrington,[6] that during periods of heavy fogs in manufacturing centers, the morbidity and mortality from respiratory disease are increased very greatly, and that, as the atmosphere clears, a sharp decline follows. In London, for example, the usual death-rate from all causes has been known to be almost doubled during a fortnight of continued dense, smoky fog, and then return to its normal figure with the advent of clear weather, the increase being due particularly to bronchitis and other affections of the respiratory tract, attributed to the irritating influence of the finely divided particles of soot and acids which accompany them.

The active constituent of the pungent, irritating vapors composing the fog of our large cities is largely sulphur dioxid. Sulphur dioxid is a heavy suffocating gas with a disagreeable odor. When inhaled in the pure state it is poisonous; when diluted with air it produces coughing and severe irritation of the air passages.

The chief symptoms of poisoning with sulphurous acid, says Cushny,[7] are those of irritation of the mucous membranes. In poisoning from the inhalation of the anhydrid, on the other hand, the symptoms are chiefly from the respiratory tract. Even in five parts in 10,000 it acts as an irritant, causing sneezing, coughing and lachrymation, and in somewhat greater concentration it becomes entirely irrespirable; still smaller quantities in the air cause bronchial irritation and catarrh when inhaled for some time.

Sulphur dioxid according to Sollmann[8] who quotes it from Lehmann's work, is very toxic by

local irritation, producing bronchitis and pneumonia. SO_2 produces extreme discomfort in proportions as small as .0001 % (0.1 % being fatal).

Not having Kionka's "Toxikologie" and Kobert's "Intoxikationen" at hand, Dr. Torald Sollmann was so kind and obliging as to place these works at the writer's disposal, from which he has made free translations.

According to Kionka,[9] 0.4 to 0.54% occasion in animals severe dyspnea; recovery, however, occurs if not too long continued. The proportion of 0.62% killed mice after six hours, 0.64% after two hours, and 0.8% even after 20 minutes. Rabbits appeared to be somewhat less susceptible to the action of sulphurous acid. They succumbed first after a proportion of 2.4 to 2.9% after four hours. The obduction shows that the pulmonary capillaries are seriously impaired, while the blood itself has undergone gross chemical changes in cases of fatal sulphurous acid poisoning in animals. When even minute quantities of the gas are inspired there is invariably difficulty of breathing (dyspnea), with cough and increased nasal secretion, etc. He says that SO_2 is a protoplasmic poison.

Kobert [10] says that the first experiments with the exact quantitative estimation of the inspired SO_2 were made by Ogata in 1884. Further experiments were made by K. B. Lehmann in 1893. When the proportion by volume is between 0.015 to 0.020 the sojourn in such an atmosphere becomes disagreeable and is with difficulty endurable to almost any one. When the proportion by volume is 0.03 to 1000 of the air it makes some persons decidedly ill after a few moments, especially parturient women, those suffering from stomach disease and susceptible persons, as an intense smarting comes on in the nose, with sneezing and coughing. The action of larger amounts was studied on animals. When the percentage of SO_2 by volume was 0.04 to the air, pronounced phenomena of poisoning showed themselves in mice, rabbits and guinea pigs. The proportion of 0.06% caused death in 6 hours and 0.08% was lethal in twenty minutes. The pathological manifestations were dyspnea, cyanosis and convulsions. Kobert mentions also the fact that the air of large factory towns contains always measurable quantities of SO_2. In winter the freshly fallen snow absorbs the sulphurous acid from the air and is slowly oxidized to sulphuric acid.

G. Wurtz has observed the constant presence of sulphur dioxid in the atmosphere of Paris, France (Compt. rend. 1885, 100, p. 1385).[11]

Dr. Sir Frederick Treves, lecturing before an assemblage for the abatement of the coal smoke nuisance, said on April 23 in London that he had seen the lungs of many persons who had lived in that city which were black from the surface to their innermost recesses. This not only made it more difficult to resist disease, but started disease. These conditions were entirely due to dirt and soot inhaled. Everybody knew the terrors of a London fog, he said. It would be merely a white mist but for the coal smoke, which gave it its fifthy, choking constituents. The London fogs killed people by thousands. Experiments showed that during a bad fog six tons of soot were deposited to the square mile.

Speaking of the effects of gaseous impurities in water, Bergey [12] says that sulphur dioxid, when present in considerable quantities, produces disease of the bones in cattle.

Kionka has observed that in small, long-continued doses the sulphites affect seriously the lungs, circulation and kidneys and have been forbidden by the Imperial Board of Health of Germany. During the recent eruptions of Mt. Pelée (1902) and Mt. Vesuvius (1906) enormous volumes of gases, largely composed of sulphur dioxid, were poured into the atmosphere, which greatly increased the suffering of frightened humanity and was the cause of suffocation and death of many thousands of victims. Like many other poisonous substances, there are persons, when exposed to sulphurous vapors in their daily work, who establish a gradual tolerance to the gas and take no notice whatever of an atmosphere in which it is present to such an extent that persons not habituated to it cannot breathe it. To some persons very small amounts of it cause difficulty of breathing in the form of wheezing and cannot be tolerated any great length of time.

It is a well-established fact that some persons have an individual idiosynerasy, on account of an abnormally hyperesthetic sensitive nasal and bronchial mucous membrane, to the inhalation of certain emanations which act as irritants, causing paroxysms of asthma. The inhalation of minute quantities of sulphur dioxid will promptly bring on an attack of asthma in certain susceptible persons. Its presence and cognizance are very important factors to those who are thus so easily affected.

Asthma is essentially a respiratory neurosis, being due to an abnormal irritability of the respiratory center, manifesting itself in a transient catarrhal congestion of the bronchioles (whose musculature is under the control of the accessorio-vagus, in which the constrictor fibers predominate), and which may be produced reflexly by irritation of the mucosa of the nose, larynx and bronchioles.

In these days of popularizing science, young students, working in chemical laboratories, should be earnestly admonished to be very careful in the handling of chlorine gas, bromine vapor and nitrous acid fumes, the inhalation of which being fraught with danger is liable to be the *fons et origo mali* — of a so-called *pars tetricus* — somewhere in the respiratory mucous membrane, giving rise, later on in life, by repeated insults, to a permanent alteration, expressed in the form of a *pars minoris resistentiæ*. Workers in bromine works are said to be peculiarly liable to asthma.

EXAMINATION OF THE AIR FOR SULPHUR DIOXID. DETECTION AND ESTIMATION OF THE GAS.

Recently (during the early mornings of January 31 and February 12), when the fogs were so bad

in this city, it being virtually in a so-called "smoke-bank," the air being very irritable and exceedingly unpleasant and at the same time unfit to breathe, the writer exposed strips of moistened blue litmus paper to the atmosphere. In a comparatively short time these papers were colored decidedly red, showing the highly acid nature of the atmosphere. The outside window panes and roofs of buildings, when touched with moistened blue litmus paper, gave promptly a decided acid reaction. The outside window panes were sprinkled with distilled water which was again collected and filtered and treated with a few drops of bromine water and barium chloride solution, when a distinct precipitate of barium sulphate was obtained. In testing rain water with blue litmus paper the latter was instantly colored red. A sample of rain water was treated with barium chloride solution which gave a characteristic whitish precipitate of barium sulphate, proving conclusively the presence of free sulphuric acid.

The most delicate means at our command for the instant detection of very minute traces of free sulphur dioxid in the air is simply by the sense of smell.

It is stated in works on analytical chemistry that paper moistened with starch paste and iodic acid solution turns blue in air containing one part of sulphur dioxid in 3,000 parts of air. This test, however, after repeated trials, is not sensitive for very minute traces of SO_2, say 5 parts or less in 10,000 volumes of air. The writer has tried patiently a number of tests in the form of test papers, but he has not found one of them reliable for the detection of minute traces of the gas. Papers containing mercurous nitrate, potassium bichromate, potassium chromate (which turns coffee brown in color, and ultimately green), etc., respond only in dense fumes of the gas.

The amount of sulphur dioxid in the atmosphere may be determined volumetrically and gravimetrically.

Volumetrically, SO_2 may be estimated by shaking a given proportion of normal solution of potassium hydroxid in a measured vessel containing air, treating the solution with sulphuric acid (1:3), adding a little starch solution and then titrating with $\frac{N}{50}$ iodine solution until a blue color is produced. One cubic centimeter iodine solution is the equivalent of 0.00064 gr. of normal SO_2.

The proportion of SO_2 may also be estimated gravimetrically by precipitation as barium sulphate by the addition of barium chloride, bromine water having been previously added. "One milligram of barium sulphate is equivalent to 0.2748 milligram of SO_2." (Harrington.)

Briefly stated, the measured capacity of the air-contained vessel and the given amount of absorbing solution, with the observed barometric pressure and observed temperature, give the estimated volume of SO_2 in the air. It being customary to express results in parts per 10,000, the rate is determined by simple proportion. Specially constructed apparatus, like those used in the determination of CO_2 in air analysis, might be used for the estimation of free SO_2.

The United States Weather Bureau should take charge of the chemical examination of the atmosphere in every large city and make daily examinations (especially during the winter months) of the air by scientifically educated persons in order to attain its highest standard of efficiency. During dense fogs the air should be analized qualitatively and quantitatively in order to determine the presence of deleterious impurities, especially that of SO_2. The object of such work would be to trace the influence of the presence of abnormally increased impurities in the air and their effect upon public health. The various diseases of the air passages, including pharyngitis, bronchitis, pneumonia and asthma, are materially influenced by meteorological conditions.

LEGISLATION AND PREVENTION OF THE POLLUTION OF THE AIR.

Man disposes of his sewage and dejecta in a most peculiar manner by casting them into the streams and large bodies of water from which he derives his water supply. In a like manner he ignorantly pollutes with poisonous gases the very air he breathes!

It stands to reason that factories, manufacturing plants and other large industrial establishments modify seriously, by their excessive smoke, the atmosphere of cities by the addition of a deleterious gas like sulphur dioxid and they should, therefore, for hygienic reasons alone, be located at some distance from cities. The importance of smoke, says Harrington, both as a promoter of disease and on account of its corrosive and disfiguring action on buildings, and also on account of the obstruction of light, has led to much legislation and to the exercise of inventive genius for devising means for the prevention of its discharge in objectionable amounts into the atmosphere of cities.

In January, 1902, when we were suffering in this city from heavy fogs, contaminated with acid, suffocating gases, the city of St. Louis had the same trouble, where the responsibility of a city for maintaining a smoke nuisance was tested in court. Because the throat and lungs of a prominent singer were injured by smoke, the city of St. Louis and its chief smoke inspector were sued in a mandamus proceeding, asking that they be compelled to abate the smoke nuisance. Litigations on account of destruction of vegetation, especially of vegetables, garden-fruit and fruit-trees, have been often instituted against smelters and sulphuric acid works.

Instead of permitting colossal quantities of sulphur dioxid to go to waste by passing into the atmosphere, thereby occasioning serious atmospheric contamination and economic damage, means and ways should be devised to recover the enormous quantities of SO_2 thus lost. Industrial application should be made of SO_2 as in the case of carbon dioxid, CO_2. Sulphur dioxid could find many a useful technical application in the arts and industries.

Writers on hygiene and sanitation have paid but little attention to the subject of air vitiation by sulphur dioxid gas, consequently their information is very limited and it is no wonder, then, that one,[6] among the rest, has made the careless statement in his otherwise very excellent work on hygiene that its effects " are exerted more on the digestive (?) than on the respiratory function."

From the presentation of all these facts it will appear evident that the weight of evidence concerning the relation of this gas to public health indicates that its effects are really " serious if not lasting " on certain susceptible persons, and that its presence in atmospheric air is a positive menace to the hygienic welfare of beings.

A CASE OF EXTENSIVE RESECTION OF THE STOMACH FOR CARCINOMA.*

BY FARRAR COBB, M.D.,
Assistant Visiting Surgeon, Massachusetts General Hospital.

No accurate knowledge of the extent of malignant disease of the stomach and the chance of its complete removal can be obtained by any other than operative methods. The case reported below is primarily of interest because it presents a strong argument in favor of operation in all cases of gastric cancer, even those which are apparently hopeless. The emaciation, severe pain and persistent vomiting, associated with the exceptionally large, palpable, epigastric mass in this case discouraged the thought of anything but a palliative gastro-jejunostomy, yet on opening the abdomen it was found possible to do a radical operation and by resecting about two-thirds of the stomach to cleanly remove the diseased area, leaving a good margin of healthy tissue. The case is interesting also from a pathological and etiological point of view, inasmuch as it furnishes a striking illustration of the ingrafting of carcinoma upon a previous gastric ulcer. The co-existence of a benign and a malignant ulcer side by side is shown in Fig. 1.

It has been estimated that fully 50% of the cases of gastric carcinoma will give a history suggestive of previous ulcer of the stomach. A majority of the cases of cancer of the stomach show direct evidence of malignant disease developing on a previous ulcer. It is thought that in this case both ulcers were benign originally and that the cancerous degeneration set in not long before the time of operation. It is interesting, however, that it was not possible to obtain a history of long standing symptoms of indigestion. Undoubtedly much of the large mass felt in the epigastrium was due to chronic inflammatory thickening of the stomach wall; if the entire mass felt had been due to cancer there probably would have been no possibility of a complete removal of the disease, because of extensive glandular metastasis. The symptoms and signs, however, before operation were so markedly those of advanced

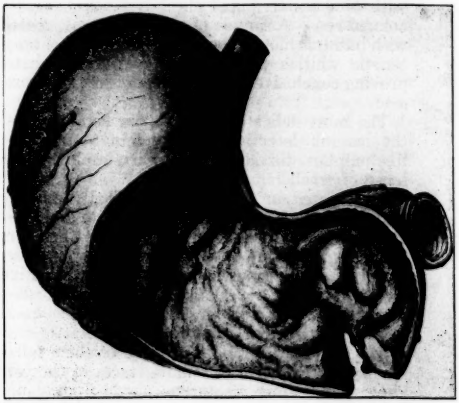

FIG. 1. The reconstructed stomach cut open from behind, showing the disease on the anterior wall.
Note the carcinomatous area near the pyloric end and the distinct benign ulcer toward the cardiac portion. Note also the marked thickening and infiltration of the anterior wall in general.

gastric carcinoma that one was justified in the belief that the case was one of hopeless cancer, demanding only a palliative operation. It is fair to state that a case presenting such a typical picture of inoperable carcinoma under the care of some physicians would not have received the benefit of a surgical consultation.

The fact that at the end of seventeen months after the operation the patient is alive and in apparently perfect health and engaged in hard manual labor justifies some hope of lasting cure. Such gratifying operative results ought to be reported, for only by so doing will practising physicians as a whole be convinced that it is their duty to send all cases of gastric carcinoma to the surgeon at the very first stages, even when the diagnosis is suspected only. As Mayo says: " In the history of medicine there is no recorded example of a case of cancer of the stomach cured by medical means. Of all diseases cancer of the stomach is most surgical, yet for some reason cases are sent to medical men, are entered in medical wards and subjected to treatment, which must result in 100% mortality.

*This case was shown at the clinical meeting of the staff of the Massachusetts General Hospital on Jan. 11, 1907, and a brief report appeared in the BOSTON MEDICAL AND SURGICAL JOURNAL, Feb. 7, 1907.

The various steps in the technique of the operation as shown may be worthy of note.

REPORT OF CASE.

History. R. J. McD., fifty-two years old, white, married, teamster by occupation, entered the South Surgical Service of the Massachusetts General Hospital on Dec. 19, 1905. By the kindness of Dr. Beach, the chief of the service, the writer was given charge of the case and allowed to operate. Family history unimportant. He had always been in good health until seven months previous, when he first began to have indigestion and pain in the epigastrium, worse after eating. When first noticed the pain would come from an hour to an hour and a half after taking food. The severity and duration of the pain depended somewhat on the kind and amount of food taken. Later there was almost continual pain in the epigastric region, gradually increasing in severity and shooting up and down the right side and into the chest and back. He had steadily lost weight. He began to vomit about six weeks before entrance and continued to vomit three or four times a day, without any definite relation to eating. The vomitus for the most part was undigested food, but dark brown material was vomited occasionally. For two weeks before entrance he had been able to retain no food and had endured great pain.

Examination. — A pale and emaciated man; weight, 108 lbs. Heart and lungs normal; liver not enlarged. A large mass, slightly movable, dull on percussion, readily palpated in the epigastrium. The muscles in the epigastrium and the right hypochondrium were held somewhat rigidly. No fluid was made out in the abdominal cavity. No glands could be felt above the clavicles. By the stomach tube 50 cm. of thick brownish fluid mixed with mucus was obtained. An examination of this showed free hydrochloric acid, 0.18%; the total acidity was 0.365%; the guaiac test showed blood. The fasting stomach contained 30 cm. Inflation showed a small and contracted stomach. Examination of the urine showed nothing abnormal. Pain and vomiting continued after entering the hospital, but was not so frequent or severe as before.

Operation. — Twenty minutes before anesthesia an injection of $\frac{1}{4}$ gr. of morphine and 1-150 gr. of atropin was given. Ether was the anesthetic used. During much of the suturing of the stomach wall it was found possible to keep the patient only lightly under ether. An incision 4 in. long was made in the median line. Upon exploration it was found that a large portion of the anterior wall of the stomach was involved in an irregular, nodular mass, which extended from the middle line well toward the pylorus and was nearer to the greater than the lesser curvature, and in addition to this the major part of the anterior wall of the stomach seemed thickened and infiltrated with disease; the whole stomach seemed sowewhat contracted. The extent of the diseased area is shown in Fig. 1, and is also shown, as well as the portion of the stomach resected, diagrammatically in Fig. 2. The stomach was not fixed by adhesions, except that in the gastrocolic omentum near the median line there were several enlarged glands adherent to the omentum and transverse colon. On microscopic examination these glands were pronounced simply inflammatory.

The steps of the operation are suggested in the diagrammatic illustrations accompanying this paper. Because of the presence of the diseased glands the gastrocolic omentum was tied off in sections first, care being taken to avoid the mid-colic artery. The enlarged glands and omentum were dissected off with care. The left gastro-epiploic artery was tied far out on the patient's left. After ligating the gastric artery as high up as possible the lesser curvature of the stomach was freed and the superior pyloric artery tied. The stomach and pylorus could then be lifted well, so that hot gauze pads could be placed in the lesser omen-

tal cavity. Two straight narrow bladed clamps were then applied at about the juncture of the pylorus and the duodenum and two similar clamps on the left end of the stomach. The position of the clamps and their relation to the diseased area is shown in Fig. 2. After

the abdominal cavity was carefully protected with gauze pads the duodenum was divided between the clamps and the pylorus and stomach with considerable omental fat and glands attached were lifted up. The stomach was then divided between the remaining

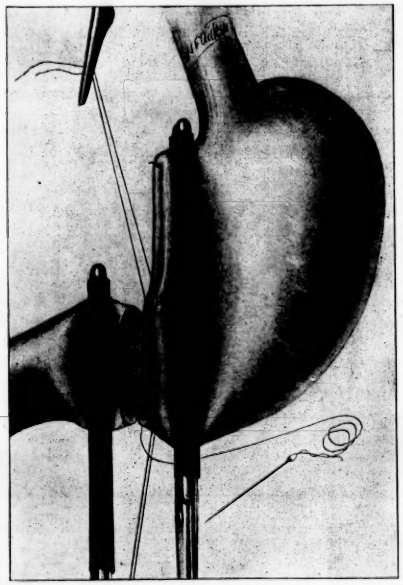

FIG. 4. The upper portion of the stomach wound has been finally closed by a continuous Cushing suture.
Note that approximation of the stomach and duodenum has been begun with the continuous through-and-through suture of catgut.

FIG. 5. Approximation completed by a continuous Cushing suture with the addition of an occasional interrupted Lembert stitch.

clamps. The cut edges of the stomach and duodenum were carefully wiped clean with sponges wet in salt solution. It was found that the stumps of the stomach and duodenum were sufficiently mobile, after freeing the duodenum as much as possible to allow approximation end to end, as shown in Figs. 3, 4 and 5. Accordingly, all idea of complete closure of the stump of the stomach and the duodenum followed by gastro-intestinal anastomosis was abandoned and the end-to-end suture method adopted, as shown. Only very rarely will the stomach be sufficiently movable to allow the use of this method without undue tension on the sutures. In the great majority of cases where such extensive resections are done it will be necessary to resort to gastro-intestinal anastomosis.

After the introduction of the guide stitches the upper or redundant portion of the stomach wound was closed by using first a continuous suture of chromicized catgut, followed by a continuous Cushing suture of Pagenstecher thread. Approximation of the duodenum to the lower portion of the stomach wound was made by a continuous suture of chromicized catgut through all the coats, followed by a continuous Cushing stitch of Pagenstecher thread. It was found necessary to use a few additional interrupted stitches of linen thread. After the removal of the pads the abdominal wound was closed in layers, without drainage, leaving a quart of hot salt solution in the peritoneal cavity.

At the end of the operation the patient's pulse rose to 120, but dropped to 70 on the third day, where it remained. The temperature did not rise above 99.2° F. after the operation and remained normal after the third day. In other words, there was no serious reaction from the operation.

After-treatment. — The after-treatment consisted of salt solution by rectum 6 oz. every four hours, together with nutrient enemata of white of egg, beef juice, peptonized milk and salt solution every eight hours. Within twenty-four hours hot water and albumen water in teaspoonful amounts were given by mouth and on the third day the patient was taking ½ oz. of water or albumen water every hour and retaining the enemata well. There was no vomiting.

The wound united by first intention and the stitches were removed on the eighth day. At this time he was taking full liquid diet freely. On the fourteenth day he sat up in bed and was up out of bed on the seventeenth day, when he was eating soft solids. Convalescence was uneventful and he was discharged one month from the day of the operation. He was then eating the regular hospital diet, with care as to amount. His weight on leaving the hospital was 118 lbs., or 10 lbs. over his weight on entrance.

Result.— This patient has been seen by me at intervals for the last sixteen months, and as was stated, he is apparently in perfect health. His present weight is 140 lbs. He eats anything and everything without any distress. He does not vomit and has no symptoms of indigestion. There is no evidence of a recurrence of the disease.

Pathological report.— The two ulcerated areas and extent of the disease are shown in Fig. 1. The large ulceration nearer the pylorus was 5.5 cm. in greatest diameter; its edges were raised and infiltrated. Microscopic examination of the indurated border showed masses of irregular tubular glands, with little fibrous or cellular tissue between them infiltrating the submucous layers of the stomach wall, — *adeno-carcinoma*. Close to this malignant ulceration was a circular depressed cicatrized area, evidently the seat of a former ulceration. Microscopic examination showed simply granulation tissue, without any evidence of new growth.

A DEPARTMENT OF SCHOOL HYGIENE.*

BY LUTHER HALSEY GULICK, M.D.,
Director of Physical Training, New York City Public Schools.

We are told by the Board of Health that over 30% of all children in the public schools have a degree of eye deformity sufficiently severe to interfere with their school work and progress from grade to grade. It is reported that in a certain school 62% of the pupils who have been there for two years or more have eye deformities. We are told that throughout the city those eye troubles increase so consistently from year to year that it is almost possible to place a certain grade by reporting upon the percentage of eye deformity found among its members.

We are told that a very considerable percentage of the children have enlarged tonsils and adenoids, and that upon the removal of these enlarged growths, pupils who have been backward very frequently develop new life and vigor, so as to enable them to recover their places in the ranks with those of their own age.

Graduates of the high schools are often denied admission to the training schools because of defective vision or hearing, physical deformity, or some other disability, which would render them as teachers undesirable risks for the city to assume.

These disabilities — many of them — can be removed, and practically all of them could have been prevented. In this fact there is presented to the Board of Education a new set of problems.

With the magnificent work of the charitable organizations of New York City, we of the Department of Education are not only most heartily in sympathy, but to them we are willing to acknowledge a deep debt of gratitude for saving to the city and to us large numbers of children — children that have been taken in the summer to the country or to the seashore, those in immediate need who have been provided for, and the like. But this work, splendid as it is, does not remove the cause of the difficulty.

The city school is, comparatively speaking, a new thing. With it new problems of lighting and seating have arisen, as well as new problems in administration. The construction of the school building involves architectural and engineering skill, and the Committee on Buildings of the Board of Education has in its employ one of the best-known American architects, whose business it is to pass upon all technical questions concerning the construction of buildings for the public school system. The size of the timbers that will support the roof of a given span, the strength of the structure in relation to its height — these are technical questions for the solution of which is demanded the skill of the technical expert.

So the Committee on Supplies, which must furnish everything for the schools from textbooks to coal, has at its head a competent business man. Under the direction of the Committee on Supplies and with the help of an able force, he attends to the purchasing and distributing of the needed materials. The purchase of coal and other commodities is not a question of psychology and pedagogy; it is a question of technical business knowledge. From whom and where to buy, in what quantities, how and when to deliver, what kinds of coal to use, what system of auditing and accounting to employ — these are technical business questions, and they must be met by a technical business expert — just as the Committee on Buildings needs for its problems an expert architect.

It is my belief that the group of problems centering about the health of school children demands technical treatment of a similar nature as that required for the departments whose duties I have just sketched. If the children's eyes are becoming defective because of lack of wisdom in the choice of type, the length of line, width of margins, the spacing between lines, it is of fundamental importance that something be done to procure the proper textbooks and thus remove the cause of the eye deformity. But for this, the advice of the technical expert is needed. It is not a matter of untrained common sense — any more than the question of the stress and strain in a building is a matter of untrained common sense. If the present modes of sitting in the New York public schools are responsible to any degree for the crooked backs that we sometimes see in children, we should know it and then change the habits of sitting. This again is a matter for the trained orthopedic surgeon. It is not a question either of psychology or pedagogy — at least not until after the diagnosis and treatment have been decided upon.

How much home study shall children of a particular age be allowed or required to do? This also is not a question of psychology or pedagogy, it is a technical question of medicine. What lessons shall children study at home? This is a question of pedagogy and school administration; but the number of hours for study, or the time when a child may do his best work — these are biological problems. They are problems that are capable of more or less exact determination.

Such facts as these lead us to the belief that there should be co-ordinated with the other activities of the Board of Education a department composed of men who are technical experts on the various questions of health in relation to school life.

There are, I believe, 63,000 children in " part time " classes in New York City. No doubt, this condition has been due to some extent because of large immigration and other causes of a similar nature; but our experience within the last year has satisfied us that a very great percentage of these classes exists because of difficulties which are removable, and it is evident that if these difficulties had been prevented or removed, these children would have been advanced normally and thus there would be at present no " part time " classes in New York City. Purely as a matter of economy, then, it would pay to take

*Read before a Conference of the Committee on the Physical Welfare of School Children, in the Kings County Medical Society Building, New York City, on June 14, 1907.

those steps which will insure that each child, as far as possible, is in condition to take advantage of the education that is provided for it so liberally and generously by this city. It is economy that the child should progress regularly in his school life, rather than remain behind year after year, blocking the lower grades of the school.

There can be no choice between health and education. Only that education is effective for use in life which is founded upon and which secures good health.

Clinical Department.

ACUTE INFLAMMATION OF TENDON SHEATHS SEQUENTIAL TO ACUTE TONSILLITIS.

BY EDWARD A. TRACY, M.D.,
Orthopedic Surgeon to Mt. Sinai Hospital, Boston.

TONSILLITIS is known to immediately precede rheumatic fever frequently; indeed, some clinicians, Osler states, have gone so far as to say there is always a primary infective trouble in the lacunæ of the tonsils, to which the rheumatic fever is secondary, the latter arising from absorption of microbes or their products.[1]

Recent writers, among them John L. Morse, of Boston, have reported cases of acute nephritis sequential to acute tonsillitis. It may be that the tonsils are a port of entry for many diseases, such as rheumatism, influenza, acute nephritis and others less known. The following cases of acute inflammation of tendon sheaths were observed by me within a year, and are reported as of possible interest to the clinician interested in the sequences of acute tonsillitis. Acute tonsillitis is certainly a disease that merits careful attention and efficient treatment at the hands of the practician. The laity, in general, look upon tonsillitis as a simple trouble, not meriting a physician's care, unless the local symptoms are severe. This view is based on a lack of medical knowledge, and should be corrected. An analogous case of harmful ignorance on the part of the laity, that presents itself to mind, is their view-point of gonorrhea. Most patients with this disease are blissfully ignorant of its dangerous nature. We should teach them its possibilities — blindness, crippled joints, heart disease, sterility, peritonitis and even death. If this knowledge were general, surely it would be better for the laity — there would be less of the disease.

Report of cases of acute teno-synovitis sequential to acute tonsillitis:

CASE I. G. R., aged twenty-eight years, sent for me to see him because of a foot trouble. No history of trauma. A week before he had suffered from acute tonsillitis, recovering from the sore throat without medical advice. He was in bed, had moderate fever, and complained of his left foot being sore in region of the ankle joint. The ankle was painful when motion was attempted, and there was marked swelling and tenderness locally over the common sheath of the peroneal tendons. The sheath was evidently inflamed and had fluid in it — it standing out from the surrounding normal tissues as if anatomically injected. After a week of treatment, salicylates and local elastic pressure, the teno-synovitis disappeared.

CASE II. J. J. D., aged thirty-five years. Had acute tonsillitis of a week's duration, with only home treatment. A few days after subsidence of the throat trouble, he had an attack of acute trouble in both feet, in the lower Achillian regions. This lasted a little over a week. The tenderness was confined to the lower third of each tendon of Achilles, and the pain occurred when these tendons were put in motion. I saw him towards the close of the attack — advised painting over the affected parts with tincture of iodine (Churchill's formula) and absolute rest till soreness disappeared. Complete recovery after three days of treatment.

Medical Progress.

PROGRESS IN PHYSIOLOGICAL CHEMISTRY.

BY J. BERGEN OGDEN, M.D., NEW YORK.

DIGESTION.

Gastric Secretion. — An extensive series of experiments by Bernt Lormquist[1] was conducted on the dog with the following operations: (1) Pawlow's small stomach; (2) a duodenal fistula; (3) a resection of the pylorus. An anastomosis between the large stomach and the duodenal fistula was obtained by means of rubber and glass tubes; this was temporary and could be removed when desired. The results obtained from experiments on this animal show that secretion in the stomach is produced by psychic and certain chemical stimuli. The latter may act on the mucosa of the stomach or on the intestine. Fats inhibit gastric secretion. The inhibition does not arise from the stomach but from the intestine. After a gastro-enterostomy, liquid substances containing much fat inhibit the gastric secretion more easily than in a normal animal. No difference is observed with other foods. In a stomach cut off from the intestine, special substances have specific actions. Water, alcohol and the ultimate products of the digestion of proteins and meat extracts provoke copious secretion. Hydrochloric acid 0.1–0.5% and natural gastric juice do not promote the flow. Lactic and butyric acids 0.5% give a marked secretion. With sodium chloride and sodium carbonate the effect is dependent on the concentration. The least active is physiological saline. With greater and less concentrations of the salt, the amount of juice is greater. Weak sodium carbonate 0.25–0.5% acts like water. With greater concentrations there is an increase. The maximum secretion is at the end of the first hour. Saliva and bile act like water. Bile precipitates pepsin and inhibits gastric digestion. The action of alcohol is most pronounced during the first thirty minutes. At this time both secretion and absorption are at their height. No other juice than gastric juice is produced. When certain substances such as sodium chloride and acids are applied locally, a profuse secretion of mucus takes place which

[1] Skand. Arch. Physiol., xviii, pp. 194-262 (1906).

combines with the hydrochloric acid and thus diminishes the acidity. In the duodenum, neither water nor sodium chloride acts on the gastric secretion. Fluid fats are very strongly inhibitory; to a less degree soda solutions. Digestion in the organism takes place more rapidly than in vitro. This is partly due to the peristaltic movement of the stomach, which mixes the food with the ferment solution, and partly to the removal of the products of digestion by resorption, which does not take place in vitro.

In "Gastric Contents" (tested by the Mett Tube Method) Sailer and Farr[2] have shown that there is an inhibition of proteolysis. The Schultz law holds only on dilution, and the diminution of the peptic activity observed with the undiluted contents is too great to be accounted for by the concentration of the enzyme. In 5 instances of the 23 examined the inhibition was overcome by a dilution of 1 to 4. In 2 cases the inhibition was complete, but digestive activity was manifested on dilution. Comparative experiments to determine the content of various substances affecting peptolysis were made in vitro with pepsin — HCl and natural gastric contents. Egg albumin, raw or coagulated, was without effect. Inhibition is absolute if the proteoses present amount to 5% by weight of the total; the effect is considerable at 2.5%, though not noticeable at 1%. Gelatin shows proteolysis at 2.5% and stops it when 10% is present. The inhibitory action of carbohydrates and fat is practically *nil*. With alcohol in a concentration of 32% there is no digestion; at 16% there is slight and below 8% no inhibition. With formaldehyde doubtful inhibition occurs in dilutions of 1 to 100 only. With higher dilutions there was no effect on the digestion. Benzoic acid (1%) and sodium benzoate (1%) are absolutely inhibitive, while in dilutions of 1 to 800 they noticeably retard digestion. Boric acid and sodium borate are without effect in any quantity. Salicylic acid is distinctly inhibitory even in small amounts. Sodium sulphite in concentrations of 1 to 1,600 slows and at 1 to 100 prevents proteolysis. Potassium nitrate inhibits at 1 to 400. The gastric antiseptic, resorcinol, is without influence in dilutions higher than 1 to 100; guaiacol carbonate is practically without effect, while creosote strongly inhibits proteolysis. The major portions of test meals were withdrawn, and the remainders diluted greatly in the stomach and immediately removed. On testing, there was a relatively greater digestive action by the gastric contents diluted in the stomach than by the correspondingly diluted (in vitro) first portion. By giving three cases of achylia gastrica and one of gastric carcinoma 200 to 500 cc. of $\frac{N}{20}$, HCl, considerable proteolytic activity was demonstrated in the contents removed fifteen minutes later.

Proteid and Carbohydrate Digestion in the Gastro-Intestinal Tract. — The investigations of London and Polowzowa[3] show that the stomach of a dog with a pyloric fistula empties itself within four to five hours. The maximum emptying takes place in the first two hours. Stomach digestion has about the same intensity during the entire digestion period. Proteid digestion in the stomach is more than twice as great as the carbohydrate digestion ($\frac{2}{3}$ to $\frac{1}{3}$). Even in the first hour of digestion proteids are split to peptones and carbohydrates to sugar. The quantity of substances passed out from the stomach as time goes on forms an ascending series of numbers while the quantity of substances digesting in the stomach forms a descending series. As a rule, carbohydrates of food are passed from the stomach more rapidly than the proteid, showing the power of selection on the part of the stomach. No absorption of proteid or carbohydrate takes place from the stomach. The quantity of gastric juice secreted is in a measure proportional to the food introduced. In the duodenum (studied by means of duodenal fistula) about $\frac{1}{3}$ to $\frac{2}{3}$ of the total digestion takes place. The activity of digestion is in a great measure directed toward the carbohydrate of the food ($\frac{1}{2}$ to $\frac{3}{4}$) while the proteid digestion is smaller. About $\frac{1}{4}$ of the absorption takes place in the duodenum in which twice as much carbohydrate as proteid is absorbed. The absorption intensity calculated upon one square centimeter per hour of duodenal mucous membrane is, for the dry substance, 19.36 mgm., for nitrogen 0.6 mgm., for nitrogenous substances 3.75 mgm., and for sugar 19.21 mgm. The intensity of absorption calculated for square centimeter per hour, for dry substances, is 54.44 mgm., for nitrogen 0.70 mgm., for nitrogenous substances 4.38 mgm., and for carbohydrate 51.57 mgm. The degree of digestion in the jejunum is about 10%, of which 16% is to be ascribed to proteid digestion and 4% to carbohydrate digestion. The degree of absorption in the jejunum amounts to about $\frac{1}{8}$ to $\frac{1}{3}$ of proteid and $\frac{1}{4}$ of carbohydrate. The dry substance dissolved in the fluids fed is absorbed in concentrations of 10%, proteid in concentrations of 1.7%, and sugar in concentrations of 4.6%. The absorption intensity of the jejunum calculated for dry substance is 10.18 mgm., for proteid 2.39 mgm., for carbohydrate 9.0 mgm., square centimeter per hour. The intensity of digestion per square centimeter per hour for dry substance is 3.54 mgm., for proteid 0.67 mgm. and for carbohydrate 3.41 mgm. About $\frac{1}{12}$ of the food is digested in the upper part of the ileum, and carbohydrate and proteid are digested about equally. Absorption takes place to the extent of about $\frac{1}{3}$, proteid and carbohydrate being absorbed equally. In the lower ileum only carbohydrate digestion takes place, the proteid digestion being completed in the upper ileum. In the upper ileum the proteids are absorbed in concentration of 1.3%, carbohydrates in concentrations of 4.0%. The intensity of absorption in the upper ileum per square centimeter per hour is, for dry substance, 9.0 mgm., for proteid 0.9 mgm. and for carbohydrate 8.4 mgm. The intensity of digestion is, for dry substance, 2.1 mgm., per square centimeter per hour, for proteids 0.31 mgm., for carbohydrates 1.9 mgm. The absorption in the lower ileum is about $\frac{1}{4}$, — for

[2] Am. Jour. Med. Sce., cxxxiii, pp. 113-126.
[3] Zeitschr. Physiol. Chem., xlix, pp. 328-396.

proteids ¾, for carbohydrates ¼. In the vicinity of the ileocecal valve, proteids are absorbed in the concentration of 3.0%, carbohydrate in concentration of 0.8%. The absorption intensity in the lower ileum for dry substance is 3.6 mgm., per square centimeter per hour, for proteids 0.57 mgm., for carbohydrates 3.26 mgm. The intensity of digestion in the lower ileum for proteids is practically *nil*, for carbohydrates it is 0.33 mgm., per square centimeter per hour.

Digestion of Fat. — From feeding experiment with dogs with stomach, pylorus, duodenum, jejunum and ileum fistulæ, Levitas[4] concludes that the digestion of fat consists of two chemical processes — cleavage of fat into fatty acids and glycerol, and the formation of fatty acid salts. Neither of these processes reaches its end point. At every point in the digestive tract there is practically equilibrium between neutral fat and fatty acids, or neutral fat, fatty acids and fatty acid salts. In the stomach fat undergoes only a very small chemical change so long as no fluid from the duodenum finds its way into the stomach. In the stomach there is no absorption. In the upper parts of the intestine the absorption of fat either as such or in the form of free fatty acid is first observed. Between lipolysis and fat absorption there exists a certain parallelism. The farther the saponification has gone the greater the absorption. Fat without admixture of other substances is well utilized by the organism, even to the extent of 96% (butter and beef fat). Lard is more poorly utilized, probably on account of its laxative action.

ACTIVATION OF TRYPTIC FERMENT.

Wohlgemuth's experiments[5] show that pancreatic juice collected from man through a fistula does not contain an active trypsin, only a proferment being present. This proferment may be activated by liver press juice, by glycocol, alanine, leucine, and slightly by tyrosine but not by glutamic or aspartic acids. Bile added to activated proferment causes an increased tryptic activity.

EREPSIN IN THE PANCREAS.

Contrary to Vernon's observations, Mays[6] finds that if trypsin destroys erepsin the action is not a very rapid one since the extracts of pancreas (cattle) on the eighth day still contained an active erepsin. Further experiments prove that extracts, one month or one year old, still possess active erepsin and also trypsin. Ammonium sulphate precipitates erepsin, for such precipitates when prepared from active ereptic pancreatic extracts are active upon peptone. The question as to whether the pancreas contains two enzymes, trypsin and erepsin, or whether one enzyme is responsible for both activities was not decided. An attempt was made to decide the question with the pancreas of the cat which is reported to contain no trypsin. This was not confirmed by Mays. Some glands and extracts possess strong ereptic power and weak tryptic action while others show the reverse, and in still others there appears to be a sort of parallelism between the two. Treatment of the glands or extracts with alcohol and ether appears to weaken both activities.

In working with fresh pancreatic juice of the dog, the same author[7] found that when the pancreatic juice of the dog is obtained from a temporary fistula it is very weakly proteolytic immediately. A pancreatic juice which would dissolve fibrin but not egg albumin (coagulated) described by Bayliss and Starling, could not be obtained by the author, for if the juice acted upon fibrin it also dissolved coagulated egg albumin slowly. Allowing the fresh juice to stand causes spontaneous formation of trypsin from the trypsinogen. It is suggested that there may be several precursers for trypsin, one which is activated by enterokinase; the others by other agents. The fresh pancreatic juice of the dog, whether activated, by intestinal extract or unactivated does not possess a very active ereptic power.

ABSORPTION OF TRYPSIN BY CASEIN.

As found by Hedin,[8] casein extracts trypsin which has been absorbed by charcoal, but it requires some time to accomplish it. The end of the extraction can be recognized by the fact that specimens filtered after different intervals of time contain the same amount of trypsin. The higher the temperature the greater the absorption, and the larger the amount of casein the greater the amount of trypsin extracted. The results support the view that protein combines with trypsin before they are broken up by the same.

Experimental work by the same author[9] indicates that the amount of trypsin neutralized by antitrypsin is independent of the dilution. The anti-body can be completely saturated by using a sufficient amount of trypsin; on the other hand, it was found impossible under the conditions employed to completely neutralize trypsin by an excess of anti-body. The amount of trypsin neutralized by a certain amount of anti-body is not constant, a small amount of anti-body neutralizing relatively more trypsin than a larger. The anti-body can be completely destroyed by 0.1% to 0.2% of acetic acid at 37° C. for about eight hours. When trypsin has been neutralized by the anti-body, it has been found impossible by the means tried to render it active again.

LIPASE.

Lipase of Intestinal Juice. — From dogs with a Thiry-Vella fistula, Boldyneff[10] has been able to obtain intestinal juice which possessed lipolytic action. This lipase is not so active as that of pancreatic juice and acts much better with emulsions of fat than upon non-emulsified fat. With milk the action is very energetic. Bile, which

[4] Zeitschr. Physiol. Chem., xlix, pp. 273-285.
[5] Biochem. Zeitschr., ii, pp. 264-270.
[6] Zeitschr. Physiol. Chem., xlix, pp. 124-187.
[7] Zeitschr. Physiol. Chem., xlix, pp. 188-201.

[9] *Ibid.*, i, pp. 475-484.
[10] Zeitschr. Physiol. Chir., l, pp. 394-413.

favors pancreatic fat cleavage, has no beneficial effect upon that of intestinal lipase. Addition of antiseptics does not markedly reduce the activity. The intestinal juice increases the fat-splitting power of pancreatic juice, and this is probably to be ascribed to intestinal lipase. After boiling the intestinal juice this action ceases. The intestinal juice obtained from the lower portions of the small intestine has no lipolytic activity.

The Inhibiting Effect of Sodium Fluoride on the Action of Lipase. — Loevenhart and Pierce [11] have found by experiment that very small amounts of sodium fluoride accelerate the hydrolysis of the fats and lower esters by the extracts. The inhibiting action of the fluoride increases as the tubes become more acid. This is probably due to the production of hydrofluoric acid. Sodium fluoride does not influence materially if at all the hydrolysis of esters by alkalies, and it only affects the hydrolysis of esters by acids as the sodium salt of any weak acid should. From this it is concluded that the fluoride probably does not inhibit the enzymic hydrolysis of the esters by reacting, with the latter. The inhibiting action of the fluoride cannot be attributed to the precipitation of calcium. The other halides of sodium and potassium, as well as many other substances investigated, do not possess an action comparable in extent to that of the fluoride. Hydrofluoric acid, and in all probability all soluble fluorides, affect these processes similarly to sodium fluoride. The greater the amount of enzyme acting the less will be the inhibiting effect of given concentration of sodium fluoride. This proves that there exists a quantitative relation between the enzyme and the fluoride. Sodium fluoride does not destroy the enzyme. Of the two modes of action to be considered, (1) that the fluoride reacts with the enzyme, (2) that it reacts with an intermediate product formed in the action of the enzyme on the ester and resulting in an increase in the stability of the intermediate compounds, the authors favor the latter view, because the enzyme is not destroyed by the fluoride, and furthermore because the inhibition varies much with different esters. It is suggested that the term " zymolyte " be applied to the substance upon which an enzyme acts instead of the term " substrate."

A so-called Coferment of Lipase. — The observation of Magnus that there exists a coferment for the action of liver extract on amyl salicylate is confirmed by Loevenhart.[12] This coferment was found to be the bile salts. When ethyl butyrate is used instead of amyl salicylate no coferment is to be noted by this method and the bile salts do not accelerate this reaction. Therefore it is not right to apply the term coferment to the bile salts with reference to lipase in general. It must be stated that they have only been proven to act as such in the hydrolysis of amyl salicylate by liver extract.

[11] Jour. Biol. Chem., ii, 397-413.
[12] *Ibid.*, ii, pp. 391-396.

CARBOHYDRATES IN THE BLOOD AND URINE.

Heptose in Human Urine. — Rosenberger [13] reports a case in which he was able to extract from the urine by means of methyl or ethyl alcohol three bodies precipitable by ether. The first was optically inactive, the second possessed dextrorotation, and the third, which at first was weakly levorotatory, became inactive. All three substances were reducing bodies and the dextrorotatory substance formed an osazone. The osazone had a melting point of 203° to 204° and an elementary composition similar to that of heptosazone.

Detection of Levulose in the Urine. — Attention is called by Jolles [14] to cases in which the polarization of samples of urine containing secreted fruit sugar is either very low or to the left and consequently the gravimetric and polarimetric methods may give very different results upon the same sample of urine. It is also pointed out that a number of other substances such as B-oxybutyric acid, glycuronic acid and many medicines which give products that are secreted through the urine may interfere seriously with the determination of the sugar by the polarimetric method. In addition, cases are reported in which fructose and glucose occur simultaneously in the urine. In view of these observations, the following methods are proposed. A modification of Selivanoff's test is suggested for the qualitative detection of the fructose. Ten cubic centimeters of urine are heated to boiling with a pinch of resorcinol and about 3 cubic centimeters of 10% hydrochloric acid. A red color indicates fructose. This test is applied in connection with the polarimetric and fermentation test, in which case its indication may be of some weight. The volumetric quantitative method for fructose is shown to be of little value, and the author therefore adopts the gravimetric method first proposed by Ost. The copper solution is made by gradually dissolving in water 17.5 gm. $CuSO_4.5\,H_2O$ to 250 gm. K_2CO_3 + 100 gm. $KHCO_3$, and the solution diluted to one liter. One hundred cubic centimeters of the copper solution + 50 cc. of the sugar-containing urine are quickly heated to boiling and kept so for ten minutes. The solution is rapidly cooled and filtered with suction through an asbestos filter. The precipitate is washed with hot water and finally with alcohol, dried, heated and reduced in hydrogen. The best results are obtained with urine of which 50 cc. reduces about 400 mgm. copper. A number of results are given, and also an algebraic expression worked out for use in calculating the polarimetric and gravimetric determinations obtained upon samples of urine containing both fructose and glucose.

A New Test for Sugar. — Fenton [15] points out that all carbohydrates of the hexose or polyhexose type yield brommethylfurfural when treated with hydrobromic acid in an appropriate condition. The furfural compound reacts with malonic ester to give a compound yielding a solu-

[13] Zeitschr. Physiol. Chem., xlix, pp. 202-209.
[14] Arch. Pharm., ccxliv, pp. 542-549.
[15] Lancet, 1907, pp. 172-215.

tion with a powerful blue fluorescence in the presence of alkali. The test is best applied to solids but may be done with liquids containing hexose in the following way: Four to 5 cc. of the liquid are poured on sufficient anhydrous calcium chloride to form a pasty mass. To the mass is added 10 cc. of toluene containing 5 drops of phosphorus tribromide. The mixture is boiled. The toluene solution is poured off, and a little malonic ester and alcohol added. The mixture is neutralized by adding alcoholic potassium hydroxide. A pink color appears. On dilution with alcohol and the addition of water, the solution exhibits a blue fluorescence. The test may be used to distinguish hexoses from pentoses.

Another Method for Sugar Determination. — Bang [16] gives a titrimetric method in which the results are as accurate as the ordinary gravimetric method; it is as follows: With a differential pipette 10 cc. of the sugar solution are measured into a flask of about 200 cc. capacity. To this 50 cc. of the copper solution are added and the total fluid boiled for three minutes. The mixture is quickly cooled and titrated with a standard hydroxylamine solution until colorless. The copper solution contains 12.5 gm. copper sulphate, purified according to Soxhlet, 250 gm. of potassium carbonate, 200 gm. potassium sulphocyanide, 50 gm. acid potassium carbonate made up to a liter with water. The hydroxylamine solution contains 6.55 gm. hydroxylamine sulphate and 200 gm. potassium sulphocyanide made up to 2 liters with water. A table is appended giving the number of milligrams of sugar for the number of cubic centimeters of hydroxylamine employed. The whole determination can be made within ten minutes.

Improved Method for the Determination of Sugar in the Blood and other Tissues. — As a result of the experimental work of Edie and Spence [17] give the following method: The blood previously collected aseptically in a sterile vessel, is defibrinated aseptically, then 50 cc. drawn off and introduced into a dialyzing tube contained in a wide-mouthed bottle of about 500 cc. capacity provided with a tightly fitting glass stopper. The dialysis is carried out in 300 to 450 cc. 0.9% sodium chloride solution, which is accurately measured, in an ice chamber. Equilibrium is reached in from forty to forty-five hours. At the end of this time the volume of the saline outside the dialysis tube is accurately measured, the bottle and dialyzing tube being then rinsed with water. The saline and washings are brought to the boiling point when an excess of boiling Fehling's solution is added and the whole kept gently boiling for five minutes. The cuprous oxide is filtered on a tarred Gooch crucible, ignited, and the reduction determined by the weight of cupric oxide thus obtained. By this method of estimating the sugar in the blood some insight has been gained as to the condition of that sugar. There is evidence to show that part of it exists as free sugar, another part as combined sugar, by this being understood those combinations of glucose with protein or lecithin, and a third part as polysaccharide or hydrolyzable sugar.

THE EFFECT OF ALCOHOL ON SOME OF THE SECRETIONS OF THE BODY.

Gastric secretion. — The experiments of Kast [18] show on pseudo-feeding of dogs and with dogs with a small accessory stomach that ethyl alcohol in small quantities and in dilutions under 10% stimulates gastric secretion. The stimulation leads to increased hydrochloric acid formation and secretion but not to a new formation of pepsin. An increased mucous production with alcohol of this strength could not be observed in man or in the dog. Concentrations of ethyl alcohol of 20% cause even a more intense gastric secretion together with an increased mucus production. With higher concentrations the secretion time is decreased and the mucus elimination increased. Alcohol over 50% strength causes intense mucus production, and a short and relatively small hydrochloric acid secretion. Alcohol over 70% leads to irritation of the mucous membrane by precipitation of the proteids. Amyl, propyl and butyl alcohols interfere with gastric digestion by inhibiting or retarding peptonization of the proteids and by irritating the mucous membrane leading to catarrh of the stomach.

Bile. — Salant [19] found that intravenous injection of alcohol into dogs does not materially change the rate of secretion of bile, and as a result does not have appreciable action on the biliary function of the hepatic cell. Alcohol injected intravenously has no influence on the content of solid constituents of the bile. When alcohol is injected into the stomach or intestines there is a marked increase in the flow of bile, and the solid elements are increased absolutely and relatively. On the biliary solids the organic constituents were increased somewhat more than the inorganic.

Hydrolytic Enzymes. — An investigation by B. Schöndorff [20] on the effect of alcohol on the content of glycogen in liver and muscle after being treated with this reagent shows that glycogen does not disappear in the liver which has been kept under alcohol. Similar results were obtained with muscle. In preserving organs for analysis under alcohol, it is better to rub them up with cooled alcohol. The diastatic ferment in the liver is not destroyed by alcohol; by removing the latter it recovers its activity. Cooling the organs to 21° C. does not destroy the activity of the ferment. In the muscles of the dog and the ox the glycogen disappears with great rapidity at room temperature. Ox muscle lost 32.7% and dog muscle 16.9% in one hour and twenty-five minutes.

Urine. — As a result of the experimental work of Hinkel and Salent,[21] they conclude that the administration of alcohol to dogs on a standard

diet causes only slight variation in the nitrogen output. The total sulphur is diminished, and the neutral sulphur increased. The ethereal sulphates are diminished, as are the phosphates. The chlorides are also somewhat diminished.

Reports of Societies.

NEW YORK PSYCHIATRICAL SOCIETY.

Stated Meeting, May 1, 1907.

The President, Dr. Adolf Meyer, in the chair.

RECOMMENDATIONS CONCERNING THE IMPROVEMENT OF MEDICO-LEGAL METHODS.

Dr. Pearce Bailey, of New York City, read this paper. It was not difficult to point out glaring defects in our Code of Criminal Procedure, judged by the standards of modern psychiatry, but legal, judicial and even medical obstacles stood in the way of remedying these defects. Any change from existing conditions would be possible only after a severe and prolonged contest by concerted forces. The fundamental error in procedure n criminal lunacy cases was the test of responsibility, *i. e.*, the knowledge of right and wrong as to the act at the time of its commission. This had been condemned by medical writers as being no test at all. Should the letter of the law be strictly observed, no lunatic could, under it, escape the full punishment for his offense, unless it could be shown that, at the time of the commission of the act, he suffered from distinct clouding of consciousness. Under this law, nevertheless, many murderers had been acquitted by reason of insanity. A loophole had been left in certain states — not New York — by adding the "uncontrollable impulse" clause. When this clause did not exist the fate of the prisoner depended upon the construction which the jury saw fit to place on the knowledge of right and wrong, as mentioned in the law. The question would naturally arise why, if so unsatisfactory, this test had stood so long with so little variation. The reasons were evident. Defective as is the knowledge of right and wrong as a test of responsibility, no better substitute had ever been offered. Another reason why this law had stood might be found in the fact that the matter is always in the hands of laymen, to whom the science of psychiatry is practically unknown. This test would have to endure so long as the Code of Criminal Procedure remained what it is to-day, for the reason that this test is as good as any single test of insanity could be. Modern psychiatry demanded that this test be, not replaced by another, but be done away with altogether. No criminal precedure could be at harmony with modern views of mental disease as long as there was no middle course between responsibility and irresponsibility, and no means of judging between them except those furnished by the knowledge of right and wrong. Nothing had been more plainly taught by recent advances in psychiatry than that different mental states make different degrees of responsibility. No law which failed to take cognizance of this fact could be satisfactory to alienists. Before undertaking any legislation in the line of amending the Code of Criminal Procedure, the Society should bend its energies toward the passage of a law which emanated from the Society and which was in the hands of the Committee at Albany. This law, if passed, would do away with many of the present evils of court procedure. It was suggested that the model plan for procedure in criminal cases would be that the question of lunacy be referred by the court to a committee of three, two members at least of which should be medical men. These men should have been certified as to their moral character and should have passed an examination as to their qualifications to pronounce on the mental conditions. There should be several such experts appointed in every judicial district. The commission thus appointed should examine into the mental state of the prisoner and report to the court. They should determine the degree of responsibility, that is, they should determine the character of the mental disease, if any, from which the defendant was suffering, and report in accordance therewith that he was fully responsible, partially responsible or irresponsible. Partial responsibility in capital cases should be sufficient to remit the death sentence, but no one who had committed murder and who was acquitted on the ground of partial responsibility should be restored to liberty under ten years. In other felonies the cases of partial responsibility should have the shorter sentence optional with the judge. The report of the committee should be handed to the court and become part of the evidence and should be the only medical expert evidence.

Dr. William Hirsch, of New York City, was of the opinion that no law, however good, would remedy the present condition of affairs, so long as we have not to deal with honest men. If it be possible for corruption or any kind of dishonesty to enter legal procedures, then the best law could not be carried out in an ideal way. On the other hand, laws, no matter how defective, could be so handled that they would answer the purposes of humanity and truth, if we have to deal with honest men. This society should direct its attention to its own profession and endeaver to raise the standard of expert testimony to such a point that dishonesty and incapacity would not be brought to bear in criminal procedures.

Dr. William Mabon, of New York City, thought the present law unsatisfactory, but so many questions were involved that it would be difficult to formulate anything that would improve conditions as they exist. He advocated referring the matter to a committee who should investigate conditions not only in this country but abroad. Nothing could be accomplished until the legal profession could be brought into closer touch with the medical profession.

Dr. A. R. Dieffendorf, of Middletown, Conn., asked Dr. Bailey to state, in closing the discussion, just what standards physicians would have for determining the degree of responsibility. He believed that neither the legal profession nor the community would permit a commission of alienists to pass upon that matter without knowing the rules which the physicians applied. He asked further if Dr. Bailey, in looking up the matter, had been able to determine how the criminal procedure in Great Britain had brought about the remarkable condition to which he referred, viz.: that there were just as many men found not guilty of first degree murder on account of insanity as were found guilty and hung.

Dr. L. Pierce Clark, of New York City, was heartily in accord with the suggestions made by Dr. Bailey and favored the appointment of a committee to study the matter very thoroughly. The law in the main was far better than what is in force at the present time, but a proper statute could be worked out only after careful study from a legal as well as from a medical viewpoint.

Dr. William L. Russell, of Poughkeepsie, N. Y., was, on the whole, in accord with the suggestions presented in the paper, and believed that a committee might, by prolonged study and the presentation of preliminary reports, bring out a discussion of the whole matter that would be very helpful. He referred to the

committee appointed two or three years ago by the American Medico-Psychological Association to confer with the American Bar Association, and thought it would be well for the committee under consideration to confer with this and other similar committees. A special procedure might be instituted to determine the advisability of detaining those who have committed murder or homicide and who have been acquitted on the ground of partial responsibility.

DR. AUGUST HOCH, of White Plains, N. Y., said it was not so much a question of making, or urging the making, of a different law in regard to the matter of responsibility, as it was of urging that a better basis be furnished for forming a medical opinion. In most cases experts would not differ so much about a given case if all had the same facts and enough facts. The divergence of opinion arose because, in many instances, the experts were working with an utterly insufficient knowledge of the case; so insufficient, very often, that in everyday practice no conscientious psychiatrist would think of forming an opinion upon it.

DR. ALLAN M. LANE HAMILTON, of New York City, thought there should be some *rapprochement* between the medical and legal professions, and to this end suggested that a committee be appointed to confer with the Appellate Division of the Supreme Court, with reference to the question in hand. Dr. Bailey had been misinformed concerning English laws. In the question of murder the facts were left to the jury, which inquired into the matter, the question of insanity coming up later. Expert witnesses were not objected to, but the final decision was left to some representative of the Crown. He agreed with Dr. Bailey concerning the ten years' confinement of individuals acquitted of murder on the ground of partial responsibility. In disputed cases, however, the time of confinement need not necessarily be ten years.

DR. CHARLES L. DANA, of New York City, did not take quite so pessimistic a view of the matter as did Dr. MacDonald. The committee, if appointed, should confer with prominent judges and lawyers, particularly criminal lawyers. The question of partial responsibility was an important one and if all alienists would accept the idea that there is such a thing as partial responsibility it would have its effect upon the method of procedure. It would be useful for the committee to undertake work along the line of devising a test for insanity which might be accepted by the legal profession.

DR. ADOLF MEYER, of New York City, said that in practically all European countries partial responsibility had been recognized in some form. The question was whether this could be so formulated as to be satisfactory to the community, for, after all, our laws were not absolutely bad. There had been heretofore too much expression of mere opinion on the part of alienists, without enough attention paid to the determination of the actual facts. The relative looseness in the determination of facts and the too liberal acceptation of hypothetical questions on the part of physicians had led to the unfavorable impressions existing to-day. It was extremely difficult to form an idea as to what should be considered sufficient facts to justify an expert in giving an opinion. Adequate observation of the persons should be in some manner invited, if not enforced, and alienists should raise among themselves the standard as to what facts are necessary to justify an opinion. It was the work of the physician to determine whether the individual had any mental disorder, and whether this disorder had anything to do with the commission of the act. The question of responsibility should be decided by the physician.

DR. PEARCE BAILEY, of New York City, in closing the discussion, said the question of responsibility should be referred to medical men, but they would have no authority more than communicating their findings to the jury. While it might be impossible to change the present procedure, yet it was well enough to look into the matter to see what could be done.

Book Reviews.

Atlas and Textbook of Human Anatomy. By DR. JOHANNES SOBOTTA, Professor of Anatomy in the University of Würzburg. Edited, with additions, by J. PLAYFAIR MCMURRICH, A.M., PH.D., Professor of Anatomy in the University of Michigan. Vols. I and II. Illustrated. Philadelphia and London: W. B. Saunders Company. 1906.

It is not to be questioned that anatomical teaching has been greatly furthered during the past few years by improved illustrating and by the use of the atlas form of presentation. We are glad to notice another admirable book of this type by Dr. Sobotta, of Würzburg, edited, with additions, by Dr. Playfair McMurrich, of the University of Michigan. It has been the aim of the author to meet the needs both of the student and the physician in the production of his work, a distinction which we are inclined to think is at times too much insisted upon. It is not an atlas designed for the special student, and therefore is not to be compared with Toldt, which is much more comprehensive. A special feature of this book is the use of several colors in the plates. Particularly has this method been used in the treatment of the muscular system with results which are altogether to be commended. The illustrations in general are wonderful reproductions of the actual dissections, and give one a peculiarly good idea of the special relations of the parts.

The first volume is especially designed for use in dissection, and the illustrations have been arranged with this end in view. It takes up the subject of bones, ligaments, joints and muscles. The second volume is concerned with splanchnology, including the heart. The general method followed is the same as in the first volume. The illustrations which naturally constitute the essential portion of such a work as this are beyond criticism and cannot fail to be of the utmost value to any student of the subject who has not immediate access to the actual dissections. The book will doubtless take its place among the very best of the atlases dealing with human anatomy, certainly so far as the illustrations are concerned. The text is somewhat brief and descriptive essentially of the plates. Its conciseness is its virtue. We see no evidence that a third volume is to appear and miss any section on the central or peripheral nervous system. This is an unfortunate omission. The book in general is an admirable example of the extraordinary perfection which modern publishing has attained.

Obstetrics for Nurses. By JOSEPH B. DELEE, A.M., M.D., Professor of Obstetrics, Northwestern University Medical School, Obstetician to Mercy, Wesley, Provident, Cook County, and Chicago Lying-in Hospitals, Lecturer in Nurses' Training School of same. Second edition, thoroughly revised and enlarged, 510 pages. Philadelphia and London: W. B. Saunders Co. 1906.

This book is just what its name indicates and as a specimen of book-work is most pleasing. It tells the nurse what to do to aid the obstetrician, and also what to do if she is alone. The instruction for the preparation of the patient and also of the lying-in room is excellent. The dietary and the glossary are valuable features.

A Text-Book of Obstetrics. By BARTON COOK HIRST, M.D., Professor of Obstetrics in the University of Pennsylvania, Gynecologist to the Howard, the Orthopedic and the Philadelphia hospitals. Fifth edition, revised and enlarged, with 767 illustrations, 40 in colors, 915 pages, octavo. Philadelphia and London: W. B. Saunders Co. 1906.

This popular book, which first appeared in November, 1898, has already reached its fifth edition, which is much enlarged and is thoroughly up to date. It is a very safe guide for the practitioner, since only those procedures which have clinical proof back of them are advised. Special attention is given to puerperal infection, and the treatment of this important subject is excellent. The subject of pyelitis of pregnancy does not have the consideration its importance demands, and so far as it is discussed the statements are not according to the weight of evidence. The book will no doubt keep its high rank among the standard text-books.

Modern Clinical Medicine — Diseases of the Digestive System. Edited by FRANK BILLINGS, M.D. An authorized translation from "Die Deutsche Klinik," under the general editorial supervision of Julius L. Salinger, M.D. With 45 illustrations. New York and London: D. Appleton & Co. 1906.

This volume includes selected articles from many of the most eminent medical men of Europe. The diseases of the digestive tract are treated fully and at the same time in a concise, practical manner. The most modern methods of diagnosis are discussed and the treatment of the various disorders receives careful consideration.

It is a book of value to the surgeon as well as to the physician, since many of the diseases included lie on the border land of medicine and surgery.

Diagnostics of Diseases of Children. By LE GRAND KERR, M.D., Professor of Diseases of Children at the Brooklyn Postgraduate Medical School. Octavo. Pp. 542. Illustrated. Philadelphia and London: W. B. Saunders Company. 1907.

The author in his preface calls attention to the facts that in infancy and early childhood diagnosis has to be based largely on the objective symptoms and that consequently their correct interpretation is of the greatest importance. The book is devoted to the diagnosis of disease in early life on these symptoms, and etiology, pathology and subjective symptomatology are touched on only incidentally. While there are many minor points which might be criticised and occasional omissions, the subject is on the whole very satisfactorily treated, and the book cannot fail to be most useful, both to the student and to the practitioner.

Atlas and Epitome of Diseases of Children. By DR. R. HECKER and DR. J. TRUMPP, of Munich. Edited, with additions, by ISAAC A. ABT, M.D., Assistant Professor of the Diseases of Children in Rush Medical College, in affiliation with the University of Chicago. With 48 colored plates, 147 black and white illustrations. Pp. 453. Philadelphia and London: W. B. Saunders Company. 1907.

When there are so many good books on pediatrics by American authors, it hardly seems necessary to translate those in other languages. If this seems advisable, however, it would seem wiser to select first-class books instead of second- or third-rate ones like this. We see nothing in this work to make it preferable to the compends by American authors, which, like all compends, are in themselves objectionable. The only thing we see in this book to commend are the colored plates, which are unusually numerous and some of which are very good.

Stöhr's Histology Arranged upon an Embryological Basis. By DR. FREDERIC T. LEWIS. 8vo, ix + 434 pp. 450 figures. Philadelphia: P. Blakiston's Son & Co. 1906.

Most authors of histologies have been contented to deal with their subjects from the standpoint of descriptive anatomy, and the facts of histogenesis have found places in their volumes only as footnotes or incidental paragraphs. Lewis's edition of Stöhr presents the novel feature of an histology built on embryological outlines. The rearrangement of this well-known text-book necessitated by such a departure has been no slight undertaking. The first part of the book, which covers the great majority of its pages, deals with cytology, general histology and special histology. The section on cytology, though largely rewritten, presents the same fundamental facts on the structure and function of cells that have been given in previous editions. The second section, that on general histology, deals with tissues not in the older, purely descriptive way, but from the genetic standpoint. The development of the mammalian body from the fertilized egg cell is briefly sketched and the differentiation of the germ layers is outlined. This affords an embryological basis for a consideration of the fundamen-

tal tissues; epithelium, mesenchyma, muscular, nervous and vascular tissue. The third section, on special histology, takes up the minute structure of the various organs of the human body somewhat as in the former editions, though here, as in previous sections, much new matter on histogenesis and even organogenesis is introduced. To hold the volume to what was approximately its former size, the general directions for making histological preparations, as well as the more detailed statements as to the preparation of the specimens from which the illustrations were taken, have been omitted or condensed into a few pages constituting the second part. Thus room has been made for the very considerable body of newly introduced embryological matter.

An examination of the volume shows it to be accurately and consistently put together, and its unusual freedom from typographical errors and misstatements reflects great credit on both author and publisher. The press is doubtless responsible for the partial loss of " side " in the explanation of Figure 26 and the faintness of Figure 138. Something might have been gained by treating the cerebral nerves (page 95) from the modern standpoint of nerve components rather than by dealing with them as composed of dorsal, lateral and ventral roots; and a description of the histogenesis of ciliated epithelium (page 31) might well have been added. But aside from a few small blemishes the volume is avowedly of very high excellence and should find ready acceptance wherever modern histology is to be studied and taught. It must not be forgotten, however, that an embryological treatment of tissues is only one step from the older descriptive standpoint toward a broad and comprehensive view of the subject, and that it is as important for the student to know the physiology of tissues as it is to be acquainted with their structure and origin. It is to be hoped that this departure in histology will be followed by further progress, in which, in addition to the structure and genesis of tissues, their physiology will receive consideration.

Epilepsy: a Study of the Idiopathic Disease. By WILLIAM ALDREN TURNER, M.D., Edin. 8vo. Pp. xiv, 272. With 13 charts and 6 illustrations. London: Macmillan & Co. 1907.

We have several times had occasion to notice in the columns of this JOURNAL the various studies on epilepsy which Dr. Turner has published in the English journals. These studies have been embodied in the volume before us, which is based upon the careful study of a thousand cases observed at the colony for epileptics at Chalfont-St. Peter, and at the National Hospital for the Paralyzed and Epileptic in Queen Square, London. The chapter on pathology is written by Dr. John Turner, from a study of one hundred and fifteen autopsies. A careful study of the literature, combined with this large personal experience, gives the stamp of authority to the work. The title is not wholly accurate, for the author follows the usual custom of including the convulsive attacks of cerebral infantile paralysis and organic disease of the brain under idiopathic epilepsy. He regards epilepsy as an organic disease of the brain, whose dominant cause is ancestral epilepsy — a disease indicative of family neuropathic degeneration. A neuropathic heredity was found in 51% and a similar heredity in 37.2%. Like most writers on the question of heredity in nervous diseases, Turner is content with noting the percentage of nervous disease in the heredity, without considering the nature of the disease or comparing the percentage with the percentage of nervous heredity in healthy persons. Thomann-Koller and Diem have found such nervous heredity in from 59% to 66.9% of healthy persons, so that the conclusions which Turner and others draw from their statistics is far from convincing as to the hereditary nature of epilepsy. He has also disregarded the teachings of Weismann as to injury of the germ plasma, which have, we believe, a very important bearing upon the genesis of epilepsy. The characteristic symptom of epilepsy, according to Turner, is the periodical recurrence of attacks of loss or impairment of consciousness, sometimes accompanied by convulsions. The convulsions are thought to be due to the deprivation of arterial blood in cortical areas, coinciding with venous and capillary stasis, in persons predisposed to nervous instability; as a consequence of this deprivation alterations are found in the large pyramidal cells of Betz. These changes lead to permanent alterations in the cortex of the nature of neuroglial sclerosis. The study of the mental states found in epilepsy is very complete and of great value. These are classed as the epileptic temperament, the paroxysmal psychoses, the psychical epileptic equivalents and the permanent interparoxysmal mental condition which leads to dementia. Much stress is laid upon the interparoxysmal conditions and the epileptic temperament, and the subject is treated more fully than in most other works, with perhaps a little undue emphasis upon the mental phenomena and the tendency to dementia from the influence of so many severe cases observed in an epileptic colony. Full consideration is given to the toxic origin of epilepsy and the author concludes that in some cases the epileptic condition may be of toxic origin. About 10% of the cases recover. In regard to treatment considerable stress is laid upon the benefits of a purin-free diet. The author, very wisely, we believe, opposes the teachings of certain New York writers who denounce the use of bromide, and upholds the efficacy of a judicious bromide treatment. Next to bromide he commends belladonna and zinc, which, in the early days, before the use of bromide, gave good results. We heartily commend the book as the most important monograph on the subject that has appeared in English since the classical work of Gowers, — a most valuable contribution to our knowledge.

As a result of the anti-spitting crusade in Pittsburg, according to the *Journal of the American Medical Association*, forty-three were arrested on the first day.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 25, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

THE RESULTS OF SECTION OF THE SYMPATHETIC IN ESSENTIAL EPILEPSY.

WHEN one carefully examines the recorded cases of epileptics treated by section of the cervical sympathetic, one is struck by the fact that the results obtained are most variable, for beside those cures which appear evident, there are numerous ameliorations and many unsuccessful results. Consequently, when this operation is undertaken, one is never sure that it will modify the attacks. And what is more important still is that the results are often published much too soon after the operation to be of any value. A number of patients have been followed for only a few weeks, a period ridiculously insufficient, inasmuch as in epilepsy one often encounters quiescence of the attacks for a considerable length of time, with or without treatment. These patients should be followed for years, which has been done for a certain number, and then usually it is found that the amelioration was merely temporary and what was taken for an improvement proved to be an unsuccessful result in the end.

Then again, one must be sure that the case is one of true epilepsy. Several published cases were afterwards found to be hystero-epileptics, while others considered as true epileptics in reality presented symptoms of associated hysteria, and it is easily understood that in these any interference might ameliorate the intensity or the frequency of the attacks. This is what appears to us not to have been sufficiently established in several published cases; it is true that very often the diagnosis is a difficult matter. These are the cases which, in the statistics, have given the greatest number of improvements or cure. In order to come to a just conclusion, one should take into consideration not simply the given result, because the precision with which the diagnosis is made, and more particularly the time during which the patient is under observation, have great importance in the determination of the ultimate results. These are the reasons why statistics differ so widely.

Alexander, in 1889, gave statistics of a series of twenty-four patients operated on by himself and obtained six cures, ten ameliorations, five unsuccessful results, two aggravations of the disease and one death by an intercurrent affection, in other words, 25% of cures. Jaboulay and Lannois, out of sixteen personal observations obtained only one cure, and this was in a hystero-epileptic, and three ameliorations; the condition of the other patients was not changed. At the Surgical Congress held in Paris in 1900, Jonnesco reported thirty-seven cases, which he had been able to follow for a considerable length of time, with the result that he obtained thirteen cures, eight improvements and sixteen unsuccessful outcomes, in other words 31% of cures. Chipault out of twenty-two cases obtained two cures and three improvements; in other words, successful results in 9%. Pilcz, out of eighty cases of essential epilepsy that he was able to follow for some time after the operation, reports 31% of doubtful improvement and not a single certain cure. Acevedo has published seven cases, all of which were improved so far as the attacks and mental condition are concerned, but the patients were followed only for a short time after the operation. White's statistics of twenty-three cases show 25% cures and 36% improvements. In several publications, Vidal records numerous instances of cure and a considerable number of improvements, while Braun, in 1901, records nine cases of sympathectomy without a single cure. In 1902 Obregia reported five cases that he followed for several years; the attacks which disappeared after the interference, recurred later and were quite as intense as before the operation. In the same year Winter collected nearly all the cases published up to that time numbering 213, but, out of these, he eliminated ninety-one, because they were reported too soon after the operation to be of any value, and out of the remaining 122 he found eight cures, or 6.6%; seventeen provisional cures, or 13.9%; twenty-three improvements, or 18.9%; and sixty-seven unsuccessful results, or 54.9%. From these results one should also eliminate all instances of hystero-epilepsy in order to seriously judge the value of section of the sympathetic, because it

should be recalled that these patients may be influenced by any operative traumatism, so that it appears that in true essential epilepsy successful results must be very few indeed.

All operators have not sufficiently considered the restrictions here mentioned, and consequently they judge sympathectomy very differently. Some, as Hahn and Dejerine, consider the operation inefficacious and dangerous. Amat and Mariani declare it useless and Eulenberg as absurd. There are a few surgeons who are partisans of the operation, Hopkins and Deaver at home, and Vidal in France. The latter gives as an explanation of his successes a series of reasons which should be mentioned. He selects his patients and only operates on those who are favorably influenced by amyl nitrite; he removes the entire cervical chain and only operates on patients who can be looked after properly after the operation.

Although post-operative care is certainly of great value, the majority of writers recognize that epileptics are little influenced by surgical therapeutics, and this is demonstrated by statistics based on properly diagnosticated cases followed for a long time, and is what might be foreseen when the present conception of epilepsy is considered, namely, that it is a syndrome rather than a morbid entity. To apply a uniform treatment to cases having a varying pathogenesis must of necessity lead to therapeutic failure.

Section of the sympathetic in essential epilepsy is, consequently, not a curative operation, for it is lacking in the pathogenic basis to be efficacious in all cases. The failure of the operation is in the first place and above all due to the fact that the cause of the attacks is not known, and secondly because one merely produces temporary disturbances in the cerebral circulation. Apropos of this, it would be most interesting to ascertain if there is any relationship between the duration of the vascular disturbances and that of the temporary improvements occasionally met with. If some knowledge on this point were obtained it might serve perhaps to aid the better understanding of the influence of circulatory disturbances in epilepsy.

It is known that cerebral anemia may have some influence in the production of the attacks in certain toxic epilepsies which, clinically, often appear essential. By the use of amyl nitrite, Vidal ascertained those cases in which anemia alone produced the attacks. In certain epileptics it stopped the attacks, and in these alone should the sympathetic be operated on. Vidal, however, did not operate on all the patients who were benefited by inhalations of this drug, and he does not consider this method as infallible. Pitres has shown by the treatment of seventeen patients that this drug could not serve for the recognition of the nature of the epilepsy and he has seen convulsions produced by it in hysterics, while it has remained without effect in supposed epileptics and in cases of large cerebral neoplasms, consequently in just the cases where it should provoke an attack according to Vidal's theory. There is no preliminary proof which can demonstrate to what extent cerebral anemia intervenes in the pathogenesis of the attack and therefore there is nothing which will indicate beforehand the effect of section of the sympathetic in a given case of epilepsy. To sum up, it may be said that this operation is, generally speaking, of little value, but that a more complete knowledge of the various forms of epilepsy and their pathogenesis might allow one to come to some conclusion relative to the advisability of operative treatment.

PLAGUE INVESTIGATION IN INDIA.

THE appalling death-rate from plague in the far East might appear a reflection on modern prophylactic medicine were it not for the great difficulty attending the treatment of the disease among the native population. That the English government is active in its efforts to abate its inroads is again shown by the last number of the *Journal of Hygiene* which contains reports on Plague Investigations in India issued by the Advisory Committee appointed by the Secretary of State for India, the Royal Society and the Lister Institute. An excellent account is given, arranged in most systematic manner, of our present knowledge of the natural history of the disease and the curious pathological and etiological facts which are now under investigation. A large number of plague rats have been studied with great care, post-mortem, with the end of determining the value of naked eye examination of suspected rats, to what extent microscopical examination alone may be relied upon for purposes of diagnosis, and finally whether the examination of a large number of plague infected rats might reveal evidence of the mode of infection on these animals, evidently a matter of the greatest importance from the standpoint of epidemiology. As a result of these experiments, the somewhat unexpected conclusion is reached that the naked eye method is decidedly superior

to the microscopic as an aid in diagnosis, and that with sufficient experience the diagnosis of plague may be made on the strength of the macroscopic appearances alone. There is apparently now no doubt that plague may be transmitted from rat to rat through the transference of fleas from a septicemic animal, and it therefore becomes important to determine the fate of the plague bacillus in the body of the rat flea; whether a single rat flea can transmit the infection; whether both male and female rat fleas can transmit the infection; whether other species of fleas can transmit it, and the mechanism by which the flea infects a healthy animal. It appears that the plague bacillus multiplies in the stomach of the rat flea, and also that a single flea may transmit the disease, whether male or female. Many other facts of the very greatest interest are deduced from this experimental study. Space does not permit us at this time to enter into a detailed consideration of all the conclusions reached, but it is evident that the rôle of the rat flea is coming to be well established, and it follows, therefore, that a beginning at least has been made toward the final extermination of the disease. We commend this admirable report to all those who may be interested in painstaking, scientific investigation on a problem of great practical import.

OPPORTUNITIES FOR MEDICAL WOMEN.

The useful place which women are now occupying in medicine is no longer to be questioned. It remains, however, to discover in what departments of the profession women are likely to be of the most service to the commuity, and reach the highest personal development. Suggestions which should be of value were given by Dr. Osler recently at the London School of Medicine for Women. On this occasion Dr. Osler pointed out that there were four channels open to women physicians. The first of these he especially commended, namely, work in connection with the laboratory branches of medicine. He thought that women were especially adapted for this type of work, and went so far as to say that much of the best work in bacteriology, histology and many departments of pathology was now being done by women. There can certainly be no question that expert women are rapidly becoming an essential adjunct of a well-equipped laboratory, whether or not they have a medical degree. In the second place there is an excellent opportunity for women in connection with institutions, and particularly those in which the insane are treated. Here, again, the last few years has seen a notable change, inasmuch as a large proportion of the hospitals for the insane are now provided with at least one woman physician. In the third place, so-called general practice offers opportunities. The diseases of women and children constitute the most natural field; but here, curiously enough, the difficulty is met that women themselves are more prone to distrust those of their own sex than men in a professional capacity. This, no doubt, time will do much to overcome. Finally, Dr. Osler gave, as the fourth field of usefulness for English women, work in India, where their duties would naturally fall in ameliorating the diseases and conditions of their own sex. The life there would be, no doubt, hard, but on the whole he thought happier than that which they would be likely to lead in their own country.

We note that Dr. Osler made no mention in his remarks of surgery as an appropriate field for women. It is in this field that many women practitioners are eager to shine, and it is, of course, a fact that much surgery is being done by women and with success. It is, however, not to be expected that pre-eminent success will be attained by women in this branch of medicine. The life of an active practising surgeon brings with it unquestionably a greater nervous strain than any other connected with the practice of medicine. If for no other reason than this, it is hardly to be expected that women practitioners in any considerable number will be able to compete in this most exacting, practical department of the profession. There remain, however, many other opportunities, some of which Dr. Osler has pointed out, which should be quite sufficient to meet the ambitions of those women who have determined to make medicine their life work, nor can we at the present time question that in certain departments of medicine there is no reason why women should not excel, and possibly in the future gradually usurp certain fields of work. The real problem before the women physicians of this and other countries is to determine the sphere of usefulness in which they may most fully develop and devote their best energies to its cultivation. They will certainly meet with no discouragement in this attempt from their colleagues of the other sex.

MEDICAL NOTES.

American Medical Editors' Association. — At the thirty-ninth annual meeting of this society, recently held at Atlantic City, sixty-four new members were elected. A committee on pub-

licity was appointed, the duty of which will be to see that the medical profession, through the medical press, is promptly informed upon all matters of general interest.

DEATHS IN THE PROFESSION. — Dr. Theodore von Jürgensen, professor of medicine and head of the Medical Polyclinic at Tübingen, has recently died at the age of sixty-seven.

Dr. Max Schueller has died at the age of sixty-four in Berlin, where at the time of his death he was in charge of the Surgical Department of the Polyclinic of the Association of Domestic Hygiene. He had of late devoted himself particularly to a study of the etiology of cancer.

DEATH-RATE FROM PHTHISIS IN ENGLAND AND WALES. — As elsewhere, recent statistics on tuberculosis show that in England and Wales there has been a decided decline in the death-rate. This has been a very general experience in civilized countries, and it is also noteworthy, as stated in the *British Medical Journal*, that there has been a very distinct tendency to a postponement of the age of death and probably therefore the age of infection. Fifty years ago the disease was most fatal in both sexes at the age-period twenty-five to thirty-five years. In females there was no change during the next two decennia, but in males the age of greatest mortality advanced to the period thirty-five to forty-five years, though in the first of these two decennia (1861-70) it was only a little more fatal at this age-period than in the age-period twenty-five to thirty-five. In the last decennium the age of greatest incidence advanced for men to the period forty-five to fifty-five years, and for women to the period thirty-five to forty-five years. What explanation can be offered for this change, we cannot venture to say; it is improbable that it can be due merely to an extension of the life of the consumptive. Whatever its explanation, it appears to mean a great saving of life during the most useful years, and must therefore represent a great gain to the nation.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 24, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 40, scarlatina 23, typhoid fever 9, measles 41, tuberculosis 50, smallpox 0, leprosy 1.

The death-rate of the reported deaths for the week ending July 24, 1907, was 15.74.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, July 20, 1907, was 158, against 219 the corresponding week of last year, showing a decrease of 61 deaths and making the death-rate for the week 13.52. Of this number 93 were males and 65 were females; 154 were white and 4 colored; 98 were born in the United States, 57 in foreign countries and 3 unknown; 34 were of American parentage, 103 of foreign parentage and 21 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 36 cases and 2 deaths; scarlatina, 32 cases and 0 deaths; typhoid fever, 16 cases and 2 deaths; measles, 47 cases and 1 death; tuberculosis, 68 cases and 18 deaths; smallpox, 1 case and 0 deaths. The deaths from pneumonia were 12, whooping cough 1, heart disease 14, bronchitis 2 and marasmus 2. There were 7 deaths from violent causes. The number of children who died under one year was 27; the number under five years, 39. The number of persons who died over sixty years of age was 29. The deaths in public institutions were 57.

There were 1 case and 4 deaths reported from cerebrospinal meningitis during the week.

A CASE OF LEPROSY. — It is stated that a case of leprosy has recently appeared at the Massachusetts General Hospital in the person of a domestic of Russian descent who went to that institution for treatment. The diagnosis has been confirmed, and she will be sent to the leper hospital on Penikese Island in Buzzards Bay.

NEW YORK.

A CENTENARIAN.—John Kelderhouse, of Schenectady, N. Y., died on July 18, at the alleged age of one hundred and seven years. He was a native of Livingston Manor, N. Y., and was the father of thirteen children.

CONTAGIOUS HOSPITAL IN BRIGHTON. — An order granting the right to the Massachusetts Homeopathic Hospital to maintain a hospital for contagious diseases in Brighton has passed the Boston Board of Aldermen.

ACCORDING TO "SCIENCE." — The Paris medical faculty has recently announced that henceforth the incumbents of the special chairs of anatomy, histology, physics, chemistry and pharmacology will not be allowed to take posts as physicians or surgeons in the hospitals. Professors of these branches will be obliged to agree to devote themselves exclusively to their educational work.

Prohibition of Use of Unclean Milk Cans. — Governor Hughes has signed the bill recently passed by the Legislature, which amends the agricultural law, so as to prohibit the use of unclean and unsanitary milk cans, the confiscation of which is directed. The bill also provides for the appointment of two milk can inspectors in New York City.

Bequests. — Among the charitable bequests in the will of the late Isador Wormser, of New York, are: $2,500 each to the Mount Sinai Hospital and the United Hebrew Charities Association, and $1,000 each to the Montefiore Home and Hospital for Chronic Invalids and to the New York Roman Catholic Orphan Asylum.

Death of the Heaviest Person in New Jersey. — Mrs. Margaret McMahon, of Newark, N. J., who is stated to have been the largest person in that state, died on July 12, at the age of forty-eight years. Her weight exceeded five hundred pounds and part of the house had to be torn away in order to move the specially constructed coffin. When the body was in the coffin it required twelve men to lift it.

Employers' Liability Law Constitutional. — In a decision handed down on July 18, Judge Adams, in the United States District Court, declared the employers' liability law constitutional. This is the first decision in the state of New York in regard to this law. It is stated that in Georgia and Kentucky federal judges have decided that the law is unconstitutional, while in Illinois its constitutionality has been upheld. Judge Adams made the decision in the suit for damages of one Patrick Lancer, a longshoreman, who was injured while at work on the steamship *Columbia*, in October, 1906; stating, in his opinion, that the plaintiff was entitled to receive damages from the steamship company.

Boat for Tuberculosis Patients. — The *Southfield*, one of the old ferry boats of the Staten Island line, which has been put out of commission by the newly constructed municipal boats, now running to that point, has been placed by Commissioner Bensel, of the Department of Docks and Ferries, at the disposal of the committee on tuberculosis of the Charity Organization Society. The boat is a large one, with double decks, and it has been fitted up as a tuberculosis camp, with hammocks, steamer chairs, etc. A trained nurse is in attendance, and once a week the committee meets on the boat and the medical members of the committee serve each two weeks in turn as visiting physicians. The patients who are sent from the various dispensaries of the city, spend the day in the fresh air, and in the evening, with the exception of a few male patients, who remain all night on board, are dismissed to their homes. Each receives from three to eight eggs and from three to eight glasses of milk daily, and at noon a meal, consisting of bread and butter, hot tea or coffee and a cooked egg, is served. In addition, the patients are permitted to bring with them whatever food they choose. Although this undertaking has been but a short time in operation, the results appear to have been very satisfactory. A member of the committee, in speaking of them, recently said: "The patients are putting on pounds and the color is coming back to whitened cheeks in a wonderful manner. Now and then a good friend sends us some fruit, magazines or flowers, and with these and the extra diet and fresh air, our patients are getting along famously."

Obituary.

EMMANUEL MENDEL, M.D.

Few who have visited Berlin during the past two decades have failed to attend the courses of Emmanuel Mendel, who has recently died at the age of sixty-seven. The immediate cause of death was a weak heart and arteriosclerosis. Mendel was born in Silesia, studied at Breslau and Berlin, and received his degree in 1861, his dissertation being on a neurological topic. From the first his preference for this branch of medicine was evident, although for some years he practised in Pankow, a suburb of Berlin, as a general practitioner. This village is now well known to physicians as the site of Mendel's asylum. During 1864, 1866 and 1870 Mendel did military service and was twice wounded. He began to teach at the University of Berlin in 1873, and early made a reputation, particularly by his course on Responsibility. His chief claim for recognition in the future will doubtless lie particularly in his work in psychiatry. Among his most notable contributions were his papers on progressive paralysis of the insane, on diseases caused by accident and on mania. He was widely sought in an expert capacity by the courts and had much to do with the codification of the German common law, particularly in relation to the lunacy laws. Personally he was genial, large-hearted and generous. His place will be hard to fill in the university in which he taught for upwards of thirty years.

Current Literature.

The Journal of the American Medical Association. June 29, 1907.

1. Smith, S. McC. *Specialization in Its Relation to General Medicine.*
2. Stucky, J. A. *Non-Operative Treatment of the Middle Turbinate.*

3. *VERHOEFF, F. H., and ELLIS, E. K. *The Bactericidal Values of Some Widely Advertised Antiseptics.*
4. EATON, F. B. *The Relative Value of Clinical Medical and Surgical Knowledge to that of the Laboratory.*
5. *LICHTY, J. A. *The Early Premonitory Symptoms of Pernicious Anemia.*

3. Verhoeff and Ellis have studied the bactericidal power of a considerable number of preparations for which antiseptic power has been claimed by the manufacturers. Some of the most widely advertised, used in full strength, failed to destroy the staphylococcus aureus after an exposure of four hours. Others showed more or less antiseptic power when acting alone, but when mixed with an equal volume of hydrocele fluid all failed to destroy the vitality of the staphylococcus aureus after an exposure of over two hours. The authors conclude that although antiseptic washes may be of some value in destroying bacteria on the surface of infected areas, thus preventing reinfection, it is impossible to find an antiseptic which will kill bacteria in the tissues in the presence of serum without injury to the tissues.

5. Lichty has studied 20 cases of pernicious anemia with reference to their early symptoms. The disease he regards as the result of a toxemia, mentioning the work of Herter, who has found evidence suggesting the B. aërogenes capsulatus in the intestinal tract as a possible producer of the hemolytic agent. The symptoms of the disorder may be placed mainly in three groups, as belonging to the digestive system, the nervous system and the cardiovascular system. In the digestive system it has long been recognized that in pernicious anemia there is often present the condition of achylia gastrica. Of the author's 20 cases achylia was present in 14, and as an early symptom in 9. Diarrhea often occurs. Nervous symptoms may occur early or late. Cases have been reported in which the spinal cord symptoms preceded the anemia. Of Lichty's 20 cases 4 showed symptoms of peripheral neuritis and 2 showed symptoms of tabes dorsalis, but the nervous symptoms were in none the first to appear. The cardiovascular symptoms, palpitation, dyspnea, etc., were present in all, but not before the diagnosis was made from the blood, except in one case. [F. W. P.]

MEDICAL RECORD.
JUNE 29, 1907.

1. VALINTINE, F. C., and TOWNSEND, T. M. *Massage of the Prostate and Stripping the Seminal Vesicles.*
2. PRAGER, P. *A New Method of Identification Superseding Dactyloscopy.*
3. DICKEY, W. A. *Diagnosis and Treatment of Gastric Ulcer.*
4. SMITH, E. L. *Asthma: Observations on Three Hundred Cases.*
5. FRIDENBERG, P. *Mental Symptoms in Nasal Affections.*
6. CLARK, L. P. *The Experimental Effects of Tobacco upon the Nervous System.*
7. *CLAPP, H. C. *Diet in Pulmonary Tuberculosis.*

7. Clapp says that diet is a most important factor in the treatment of tuberculosis. A consumptive is much more likely to eat too little than too much. Systematic overfeeding and proper digestion of the food are the accepted remedies. The food must be palatable and well served and the amount must vary with the patient and his circumstances. The outdoor air will enable him to assimilate large amounts. Milk and eggs are the best foods to produce fats, which are most necessary to the patient. The author advocates three solid meals a day, with lunches between of milk and eggs, about three quarts of milk and six eggs a day being taken. Fresh meats are especially necessary for these patients, but a mixed diet is undoubtedly the best borne. Meat juice is valuable. Pastry, candy, fried foods and cabbage should be let alone. Alcohol is not advisable, but coffee, tea and chocolate may be taken moderately.

6. BRYANT, W. S. *The Radical Mastoid Operation.*
7. *DUNHAM, J. D. *The Diagnosis and Treatment of Gastric Neuroses.*

7. Dunham's article is a plea for more careful study and more rational treatment in the cases of gastric neuroses, which make up the great majority of all cases with stomach symptoms. The diagnosis requires a more general use of the stomach tube to exclude the presence of organic disease. Certain special forms of neuroses are mentioned. Nervous anorexia or complete loss of the sensation of hunger is difficult to overcome and may simulate early tuberculosis or cancer. The treatment requires that all possible methods of diagnosis be employed and that the condition be fully explained to the patient; then, careful feeding with small amounts at frequent intervals, the three main meals of the day being preceded by a bitter tonic, will usually effect a cure. In the more advanced cases residence in a sanatorium or even forced feeding by the stomach tube may be necessary. Nervous vomiting is a serious condition, the diagnosis of which must be made by exclusion, and if possible by detection of a cause of the attack in some nervous influence. The vomiting usually occurs easily, without effort, and without regard to the kind of food ingested. Hospital treatment, high frequency current, forced feeding and hydrotherapy will effect a cure in most cases. Under the heading of neurasthenia gastrica are included many ill-defined disturbances of digestion of undoubted nervous origin, following debilitating influences and causing varied symptoms. The diagnosis is to be obtained by close study with special care to exclude ulcer. Where a positive diagnosis is impossible, a rest cure should be instituted as appropriate either to ulcer or to neurosis. Some patients may be relieved by simple reassurance. In more cases the improvement is slow. Residence in a hospital is desirable, also cold baths, systematic feeding, tonics, rest and methods of suggestion. [F. W. P.]

THE LANCET.
JUNE 22, 1907.

1. BARKER, A. E. J. *The Nature and Treatment of Piles.*
2. SAVILL, T. D. *The Treatment of Hysteria.*
3. *ROUGHTON, E. W., LEGG, T. P., and EMERY, W. D'E. *Two Cases of Excision of Ruptured Spleen.*
4. *HOWELL, C. M. H. *A Consideration of Some Symptoms which may be Produced by Seventh Cervical Ribs.*
5. SCATLIFF, H. H. E., HOBHOUSE, E., and BUSHNELL, F. G. *A Case of Acute Leukæmia (Lymphocythemia).*
6. COLMAN, H. C., and MARSHALL, C. R. *A Dangerous Dry Shampoo.*

3. Roughton, Legg and Emery report in detail operations on two cases, respectively aged seven and twelve years, of ruptured spleen. In all such cases the writer believes that unless the injury is very slight, excision of the spleen *in toto* is best. In the reported cases where a healthy spleen was removed in children, recovery has been generally rapid. There are three classes of cases: (1) convalescence is rapid and complete; (2) serious symptoms develop for a while, followed by a complete recovery, and (3) an intermediate group characterized by enlargement of lymph glands, anemia, some enlargement of the thyroid, emaciation with, later, a rapid recovery. In these two cases here reported, the post-operative symptoms were rapid emaciation and weakness, great anemia, drowsiness and intermittent elevation of temperature. The reds were 3,652,000 and the hemoglobin 60% immediately after the operation; regeneration began six days later, with a complete restoration to normal in a month. The leucocytes remained at about 23,000 for six days and then dropped to 10,000, with a secondary rise a day later to 17,000 and a gradual reduction to normal. There were a few nucleated red cells and myelocytes. There was no eosinophilia after operation. There was a decided lymphocytosis throughout, which has persisted to the present, three years after the operation.

4. Howell gives results of his studies of 16 cases of cervical ribs. The most important point in these anomalies is that even a rudimentary cervical rib may cause pressure on the brachial plexus with marked symptoms. In all his cases there was pain, numbness and weakness or tingling sensations in one hand; all these symptoms disappeared after the removal of the ribs by operation. A careful differential diagnosis must be made from syringomyelia, anterior poliomyelitis, peripheral neuritis, and certain other brachial palsies. Ocular changes, common in syringo-myelia, are unknown in this condition; any sensory change at once excludes poliomyelitis or progressive muscular atrophy. Scoliosis may be present in some cases. The x-ray will generally clear up all doubt as to the condition. [J. B. H.]

British Medical Journal.

7. Macewen, W. *The Role of the Various Elements in the Development and Regeneration of Bone.*

1. Canthe gives brief summaries of the diagnosis and treatment of some of the more common tropical diseases, such as malaria, in which he mentions his own case of "malarial neuritis," hemoglobinuria, dysentery and sprue, hepatic abscess and others. The various descriptions are brief, but are of value to the general practitioner on account of their practical nature.

4. Maclean calls attention to the fact that while Fehling's test for sugar in aqueous solution is the most delicate one we have, in certain urines, with small amounts of sugar, this test shows no reduction, owing to the fact that kreatinin is capable of holding in solution a certain amount of the reduced suboxide of copper. Kreatinin itself in more than normal amounts (1-2 gm. per day), will act as a reducing agent on copper, giving rise to various ambiguous reactions sometimes seen in urines known to be free from sugar. Contrary to the idea generally held, uric acid and urates do not have any reducing action on copper; phosphates, on the other hand, can do this to a slight extent. To avoid errors caused by these substances, all of which predominate in urines of a high specific gravity, any urine of a high specific gravity, 1,028-30, should be diluted down to 1015 before testing. By so doing many errors will be avoided. [J. B. H.]

7. Herschel, K. *A New Ear Electrode.*

1. Von Leyden and Bergell give a preliminary report of some experiments on the injection of a newly discovered liver ferment into tumors. This ferment is obtained from the freshly macerated livers of animals. It has little effect on isolated carcinomatous tissue, but injected *intra vitam* into the tumor mass it causes an extensive and markedly selective destruction of the cancerous tissue, leaving an unevenly marked boundary between sound and diseased tissue. This proteolytic ferment was injected into three cases, one a large sarcoma of the neck, another a recurrent cancer of the breast, and a third a carcinoma of the uterus. All these cases had numerous metastases and subsequently came to autopsy. In each case the injection was shown to have caused an extensive destruction of tissue resembling the necrosis and cellular solution due to enzymotic action.

3. Bassenge found typhoid toxin, prepared after the method advised by Brieger, effective after having been carried for two years on German naval vessels in tropical seas. This toxin is prepared by shaking typhoid bacilli in distilled water for twenty-four hours and filtering off the bacilli. It forms, according to the author, a sure and practicable means of protection against typhoid and one whose efficiency is not affected by change of climate and age. [L. G. M.]

1. Spielmeyer shows the points of resemblance between sleeping-sickness and general paresis, clinical and anatomical. The most striking of these is the lymphocytosis of the spinal fluid and the marked infiltration with lymphoid and plasma cells in the cortex, especially about the vessels. Degeneration of the pyramidal tracts, so common in paresis, was lacking in Spielmeyer's cases of sleeping-sickness. The relation of syphilis to trypanosome infections is interesting in this connection, for on the one hand syphilis is generally considered the most important cause of paresis and tabes, on the other, the author has produced the lesions of tabes in dogs by infection with the organism of tsetse-fly disease (trypanosoma Brucei). Should Schaudinn's theory that the spirocheta pallida is closely related to the trypanosomes be substantiated, the reason for this similarity in the lesions will be apparent.

2. This article by Groedel describes, with the aid of diagrams, the results of x-ray examinations of the stomach, chiefly after the ingestion of food mixed with bismuth. By the author's method of orthodiascopy of the stomach, exact measurements are possible. The x-ray examination gives a much more exact idea of the position and shape of the stomach than does the common method of inflation with air.

6. Kayser states that in using his method of cultivating typhoid bacilli from the blood (5 cc. sterilized ox-bile incubated 20 hours wth 2.5 cc. blood and then plated on Endo's or Conradi-Drigalski's media) it is best, in case of a negative result, to make other plates from the bile mixture at the end of 48 and 72 hours, because in some instances growth may be delayed. The use of pure bile salts instead of bile, as advocated by Meyerstein, has given inferior results in his hands. Kayser reports 94% of 69 cases positive by this method in the first week; the frequency with which bacilli can be demonstrated in the blood diminishes progressively as the disease goes on, falling to 43% in the third week.

8. Braatz has collected 6 cases from the literature in which the symptoms of lead poisoning followed gun-shot wounds at a variable period and disappeared after the removal of the bullet.

9. In Witzenhausen's cases phimosis in infants caused distention of the bladder with obstinate constipation, frequent urination and sometimes marasmus and convulsions. The prompt recovery from these symptoms after circumcision is worthy of note. [W. T.]

THERAPIE DER GEGENWART.
MAY, 1907.

1. FÜRBRINGER, P. *The Treatment of Bronchial Asthma.*
2. *TEICHMANN, F. *Therapeutic Uses of Digalen.*
3. *MEYER, H. *The Treatment of Chronic Constipation with Regulin.*
4. *KLEMPERER, G. *Escalin, a Drug for Checking Gastro-intestinal Hemorrhages and to Promote Healing in Gastric Ulcer.*

6. *MÜHSAM, R. *The Treatment of the Urinary Retention of the Prostatic by Means of Suprapubic Fistula and Cystopexy.*

2. Teichmann reports on the results of the use of digalen in Stadelmann's clinic. Digalen is a pure crystalline preparation of digitoxin in a soluble form. When given by mouth it has much the same effect as preparations of digitalis; it is not adapted for subcutaneous or intramuscular use, because it causes local irritation. When given intravenously the effect is almost immediate, and there is a lengthening of diastole, the systole is stronger, the blood pressure rises and diuresis takes place. The rise in blood pressure is due partly to a vasomotor constriction which affects also the coronary arteries. For this reason the intravenous use of digalen is contraindicated in advanced cases of myocarditis and especially in coronary sclerosis, where the sudden rise in the peripheral resistance combined with a smaller supply of blood to the heart may result in collapse. The intravenous use of digalen represents a great advance in the treatment of acute cardiac failure where immediate stimulation of the heart muscle is required.

3. Meyer's results from the use of regulin (agar-agar plus a small amount of cascara) in the treatment of chronic constipation have been excellent, like those of most previous writers on the subject. Out of 71 cases 62 were favorably influenced, so that he considers it by far the best drug for constipation. Its special advantages lie in the fact that it is not necessary to increase the dose after long continued use, and that its action is almost wholly mechanical. The dose is a teaspoonful to three dessertspoonfuls a day, according to circumstances. It is best given in soup, mashed potato or apple sauce.

4. In escalin, Klemperer recommends an absolutely non-poisonous substitute for bismuth subnitrate in the treatment of gastric ulcer. It consists of very finely powdered aluminum mixed with glycerin and given in emulsion with water. The dose is 10 gm. Animal experiments showed that the aluminum forms a dense coating over the mucous membrane and is quite adherent to it. Twelve cases of profuse gastric hemorrhages all recovered under the use of escalin, and what is especially noteworthy, the blood soon disappeared from the feces, even for delicate chemical tests. In simple gastric ulcer without hemorrhages, the results were also very encouraging, for all recovered and the occult blood disappeared from the feces within 24 hours after the reappearance of the aluminum. The action of escalin is to make a thick crust over the ulcer, thereby stopping the bleeding and giving a chance for healing to take place.

6. The operation of cystopexy or attaching the bladder to the anterior abdominal wall has a beneficial effect on urinary retention secondary to hypertrophy of the prostate, apparently because it exerts a pull on the opening of the urethra into the bladder. In an old man whose general condition was so bad that prostatectomy was out of the question, Mühsam achieved a cure by the combination of suprapubic fistula according to Witzel, and cystopexy. Three months after the operation the fistula was closed and the function of the bladder normal. [W. T.]

2. In a paper published in 1906 (reviewed in this JOURNAL, 1907, Vol. CLVI, p. 362) Askanazy discussed the occurrence of hematuria associated with chronic nephritis. He considered the hemorrhage to be the result of paroxysmal congestion intensified by the increased blood pressure of the condition. Kusumoto, in this paper, describes a case in which he found rupture of the small vessels of the pelvis of the kidney, which vessels histologically appeared to be veins. He does not think that the congestion theory advanced by Askanazy can be a satisfactory explanation of the condition, since hematuria is relatively uncommon in these forms of nephritis in which high tension is a very constant feature. Another explanation advanced is that the hemorrhage comes from the increased venous stasis associated with the act of defecation. However, physiologically, any increase in general pressure is associated with contraction of the renal vessels, but this matter of compensatory function may be absent in the vessels of chronic nephritis; consequently with the increase in general pressure, if there is associated a temporary venous stasis, this may be sufficient to produce rupture of the vessels. At any rate, in his case he has shown the actual anatomical rupture of veins in the pelvis of the kidney, without any associated inflammatory change.

3. The action of the x-rays on the metabolism in cases of leukemia has been very extensively studied, and especially the changes in the excretion of uric acid. However, these studies have given rather unsatisfactory results, because the patients are in such a physical conditions owing to the disease, that strict diet regulations cannot be carried out. Linser and Sick have studied the effect of the x-rays on the uric acid and purin bases in patients with normal blood condition, in which the diet could be strictly controlled; the cases were under treatment for local skin conditions. To exclude the exogenous purin bases a diet was used free from nuclein. Instead of short exposures to the x-rays, long exposures (4 to 8 hours) with the tube 100 to 150 cm. distant were used. It was found that these individuals showed as a result a decreased number of leucocytes associated with an increase of the total nitrogen excretion and an increase in uric acid and purin bases. They believed that both the leucocytes in the circulating blood and in the leucocytic tissue are affected. It is probable that this destructive action on the leucocytes is due to the formation of some toxic substance soluble and circulating in the blood. This view is supported by the long continuance of the leukopenia after exposure to x-ray cases and the incubation period necessary before the effect of the x-ray is evident. They found during exposure to the x-ray also an increase in the uric acid present in the circulating blood.

5. Here are recorded blood pressure observations on a number of cases representing various pathological conditions. Some of these are of considerable interest and

they make an addition to our knowledge of the blood pressure changes in certain conditions. The first case was one of tuberculous meningitis, in which cessation of voluntary respiration was followed by a greatly increased blood pressure (220 mm. of mercury). Artificial respiration produced at first a fall, followed by a rise to 200 mm. of mercury. These fluctuations in pressure continued, with the level constantly falling, until the patient died, two hours and twenty minutes after the beginning of the observations. In a case of angina pectoris the attacks were accompanied by rises in blood pressure. Both the attacks and the rise in blood pressure were favorably influenced by mechanical artificial respiration. In another case with the same condition there was a decreased blood pressure during the attack. A case of bronchial asthma showed an increased blood pressure and the attacks disappeared during artificial respiration. Other cases illustrated the possibility of the association of acute cardiac insufficiency accompanied by edema of the lungs and chronic passive congestion of the other organs with increased blood pressure. In a case of acute alcoholism the blood pressure was sub-normal, as low as 78 mm. of mercury, and the same was true of a case of tobacco poisoning. Four cases of high blood pressure in young individuals are reported. However, in these there is no report of the urinary condition and the presence of a chronic nephritis as a possible cause does not seem to have been considered. No general conclusions are attempted on the basis of these scattering observations.

6. These two observers in patients on low diet and in bed have determined the total fluid and sodium chloride content of the food and of the urine daily, and observed the effect of increasing at times the salt given. In pneumonia they find a decreased elimination of salt uninfluenced by an increase in salt given by mouth. The cause of this salt retention, they think, lies not in a primary retention of water, but in a peculiarity of the tissue and pneumonic exudate. In cases with pleuritic exudates they find no salt retention, but an increase in the salt output after increasing the salt intake. Salt can even act as a diuretic in these cases. In heart disease the water and salt excretion depends upon the circulatory condition, but each can be independent of the other. Salt increase in the diet does not lead to water retention, but can even have the opposite effect. The salt content of non-nephritic exudates, transudates and edema is frequently considerably higher than that of the edema of renal disease. In nephritis considerable variation was found in individual cases, but in general there is a good salt elimination which may be entirely independent of the water excretion. In most of these cases an increase in the salt of the diet increases the output of salt in the urine, and the relations of the salt excretion give no index of the severity or kind of renal lesion. The theory of a primary salt retention as a cause of edema is not supported by these observations. The edema appears rather to be dependent upon vascular changes. In no case were injurious effects observed from increasing the salt in the food, and consequently the salt-poor diet, as advised by others, seems to these observers unjustified, unless one means by such a diet merely a non-irritating diet, such as has been long used in nephritic cases. For them there is no virtue in a simple salt reduction in the diet.

7. Rogge and Müller point out the very great frequency of the association of tabes dorsalis and circulatory disease, especially disease of the aorta and aortic valves. In 24 selected cases two thirds showed this combination, and in one third there was aortic aneurysm. Another striking fact was the frequency with which the circulatory lesions were symptomatically latent. This association may explain some cases of sudden death in tabes and some of the so-called cardiac crises. It is also a further evidence of a syphilitic etiology, since we know that syphilis is a cause of such circulatory lesions, and rheumatism was strikingly uncommon in the past history of these cases. Not infrequently both conditions (spinal and circulatory) have been overlooked until the sudden development of a cerebral lesion ensued.

8. In cases of hydrocephalus following epidemic meningitis, Schultz has practised cerebral puncture. The result is a clearing of the sensorium, improvement of the appetite, cessation of convulsions and a general betterment of the condition. However, these are transitory, and most cases will probably finally die in spite of repeated tappings.

11. Schmoll has studied two cases by the graphic method, and concludes from these that paroxysmal tachycardia is due to the presence of extra systoles, which have their origin in the auriculo-ventricular bundle of His. [H. A. C.]

REVUE DE CHIRURGIE.

1. The authors have collected the histories of 48 cases of persistent priapism from the literature, to which they add one personal observation. Priapism lasting weeks or months may be of various origins: (1) nervous; (2) traumatic; (3) inflammatory; (4) leukemic; (5) idiopathic. The most frequent cause is found in leukemia. In the majority of instances only the corpora cavernosa are involved, though occasionally the spongiosum has been found congested, in which case there is usually difficulty with urination. The affection is often extremely painful. Whether the mechanism by which the condition is brought on be by thombosis, by a hematoma compressing the return blood vessels, or by nervous impulses, cannot be decided in the light of our present knowledge. Recovery is the rule. Of the 48 cases collected, 31 recovered spontaneously, 5 dying later of leukemia. Ten cases were cured by incision. The final result in most cases is probably loss of function. Operation is to be advised.

3. Schwartz and Dreyfus report the case of a man of nineteen who, falling under the wheels of a wagon, sustained a fatal rupture of the lung without fracture of any rib. A marked feature of such cases is emphysema of the neck and upper chest, the air reaching this location from the peribronchial and mediastinal tissues. Such cases nearly always occur in children or in young adults. The visceral pleura is often found intact, or presenting a few minute ruptures. Subpleural ecchymoses are numerous. In the author's case there was but little hemoptysis and only a moderate amount of blood free in the pleural cavity. [Such cases present a condition a step more critical, but in every way comparable with those of so-called traumatic asphyxia from compression of the thorax.]

4. The authors report the result of 19 cases of extirpation of anal and rectal cancer by the perineal route. The immediate operative result was favorable in all but 2 cases, one of which died of peritonitis, the other of collapse. The end results in 10 cases, lasting from four months to eight years after operation, showed either good health without recurrence, or death from some intercurrent disease. An artificial anus is to be avoided whenever possible and in the above series was used but once.

5. Hardoüin reports the case of a man of forty-eight who, three weeks after a severe abdominal trauma, noticed a mass in the epigastrium, somewhat to the left of the middle line. This was accompanied from time to time by violent colic, vomiting, distention and tenderness. There were neither sugar nor albumin in the urine. On distention, the stomach was found to lie in front of the tumor. At operation two liters of fluid were evacuated from a pancreatic cyst, the wall of which was found everywhere firmly adherent to neighboring structures. A second incision was made in the left loin, and the cyst drained through this, the original incision being closed. Recovery was prompt and in three months the fistula had closed. This procedure of bringing the walls of a large adherent cyst to the edges of a skin wound (called "marsupialization") is strongly advocated when dissection and complete removal are impossible. [W. C. Q.]

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED JULY 3, 1907.

EAGER, J. M., assistant surgeon-general. Granted leave of absence for one month from July 8, 1907. July 3, 1907.

MCINTOSH, W. P., surgeon. Granted leave of absence for one month and fifteen days from July 25, 1907. June 26, 1907.

STIMPSON, W. G., surgeon. Directed to proceed to Bellingham, Wash., for special temporary duty, upon completion of which to rejoin his station. June 27, 1907.

STIMPSON, W. G., surgeon. Leave of absence granted Surgeon Stimpson for fifteen days amended to read for twelve days only.

FRICK, L. D., passed assistant surgeon. Granted leave of absence for three days from June 22, 1907, under paragraph 191, service regulations.

BILLINGS, W. C., passed assistant surgeon. Granted three days' extension leave of absence. July 1, 1907.

STANSFIELD, H. A., passed assistant surgeon. Relieved from duty at Havana, Cuba, and directed to report at the Bureau in Washington, D. C., July 3, 1907.

SCHERESCHEWSKY, J. W., passed assistant surgeon. Granted leave of absence for one month from Aug. 1, 1907. July 3, 1907.

SALMON, T. W., assistant surgeon. Directed to proceed to Richford, Vt., for special temporary duty, upon completion of which to rejoin his station at Boston. July 2, 1907.

SWEET, E. A., assistant surgeon. Leave of absence granted Assistant Surgeon Sweet for fourteen days amended to read for eight days only.

SIMPSON, FRIENCH, assistant surgeon. Granted leave of absence for seven days from June 22, 1907, under paragraph 191, service regulations.

SAFFORD, M. V., acting assistant surgeon. Directed to proceed to Richford, Vt., for special temporary duty, upon completion of which to rejoin his station at Boston. July 2, 1907.

STEVENSON, J. W., acting assistant surgeon. Granted leave of absence for twenty days from July 5, 1907, and excused without pay for the further period of two months. June 25, 1907.

STODDARD, C. S., acting assistant surgeon. Granted leave of absence for thirty days from May 20, 1907. June 28, 1907.

TARBELL, B. C., acting assistant surgeon. Leave of absence granted Acting Assistant Surgeon Tarbell for ten days from April 15, 1907, revoked. Granted leave for thirty days from May 15. July 2, 1907.

BOARD CONVENED.

A board of medical officers was convened to meet at Richford, Vt., for the examination of an alien immigrant. Detail for the board: Assistant Surgeon T. W. Salmon, chairman; Acting Assistant Surgeon M. V. Safford; Acting Assistant Surgeon J. H. Hamilton, recorder.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING JULY 20, 1907.

W. A. MCCLURG, medical director. Commissioned medical director from June 16, 1607.

F. W. F. WIEBER, surgeon. Detached from command of naval hospital, Pensacola, and ordered to command the naval hospital, Canacao, P. I., sailing from San Francisco about August 8.

G. H. MCCONNON, assistant surgeon. Resignation accepted to take effect Aug. 1, 1907.

C. G. ALDERMAN, assistant surgeon. Appointed assistant surgeon from July 9, 1907.

R. A. CAMPBELL, acting assistant surgeon. Detached from duty on the Midway Islands and ordered home to wait orders.

F. P. W. HOUGH, L. W. MCGUIRE, acting assistant surgeons. Appointed acting assistant surgeons from July 12, 1907.

M. C. BAKER, assistant surgeon. Appointed assistant surgeon from July 12, 1907.

G. H. MCCONNON, assistant surgeon. Detached from the "Missouri" July 25 and ordered home to wait orders.

A. MCK. JONES, acting assistant surgeon. Orders of June 12 revoked. Detached from the naval recruiting station, Chattanooga, Tenn., and ordered to the Naval Medical School Hospital, Washington, D. C., for treatment.

H. R. HERMESCH, M. BOLAND, H. L. DOLLARD, E. P. HUFF, H. L. SMITH, W. G. STEADMAN, JR., M. DONELSON, E. E. CURTIS, D. H. CASTO, assistant surgeons. Appointed assistant surgeons from July 12, 1907.

J. D. MILLIGAN, pharmacist. Unexpired portion of sick leave revoked. Ordered to the "Fish Hawk" July 27.

RECENT DEATHS.

DR. SAMUEL WIMPELBERG, of New York, died suddenly in Roosevelt Hospital in that city on July 12. He was graduated from the Jefferson Medical College, Philadelphia, in 1883, and till recently had practised at the Getty House, Yonkers, N. Y.

DR. CHARLES HODGE BOARDMAN, of Brooklyn, N. Y., who was a son of the late Rev. H. H. Boardman, D.D., of Philadelphia, died on July 16.

Address.

THE PAST, PRESENT AND FUTURE OF TUBERCULOSIS.*

BY FREDERICK C. SHATTUCK, M.D., BOSTON

THERE are obvious reasons why the honor of being asked to prepare the Shattuck lecture is peculiarly grateful to me. The terms of the will under which the society has established that lectureship provide that the income of the bequest shall be applied to the "collection and publication annually of historical or other essays on the climate of said Commonwealth, on the diseases of its inhabitants and on such other subjects as the said society or its government may select."

It is just one hundred years since Dr. Shattuck, having taken the degree of M.D. at the University of Pennsylvania, at that time the chief medical school of the country, settled in Boston. His father, Dr. Benjamin Shattuck, was a country practitioner in Templeton, Worcester County, an A.B. of Harvard in 1765, but apparently had no degree of M.D., there being no institution in the country at that time capable of granting it, and his circumstances not permitting him to cross the water to secure it.

His life was arduous and was brought to an end at fifty-three, I believe by tuberculosis. This disease also proved fatal to Dr. George C. Shattuck's first wife, probably to one or more young children, certainly to a daughter of twelve. Of seven children, the eldest alone grew up and married. Families of old New England stock are smaller to-day than formerly; but infant mortality is far less among them, so that the actual decrease in this stock is probably not as great as the smaller number of children would seem to indicate. However this may be, certain it is that the rigorous, changeable climate of New England has long had an evil reputation as being favorable to tubercular disease. This fact, in connection with the loss which consumption inflicted upon Dr. Shattuck's family, his desire to do what he could to make his beloved state healthier and happier, and the prominence which the prevention and cure of tuberculosis has assumed of late years in this community, as well as throughout the world, determined me to choose as my subject for the evening, "The Past, Present and Future of Tuberculosis." The subject may be well worn. It is, however, of vital interest, and I do not feel that I shall wear it out, whatever the effect of my remarks may be upon you.

Tuberculosis is no modern disease, its most frequent form and localization in the lungs — consumption — having been recognized and dreaded alike by the profession and the laity in the remotest times of which we have written record. And yet so universal and constant has been its presence in settled and civilized communities, so steady, sure and apparently unavoidable its ravages, that familiarity, although it did not breed contempt, did breed a certain indifference. Until the most recent times it was regarded as one of the manifestations of the inscrutable will of God, almost inevitably fatal, — a part of the necessary order of nature.

Kismet was on the lips of Christian, Jew and Mohammedan alike with regard to consumption. Thus, although dreaded, it was — and is — far less so than those infections which visit us only from time to time and to whose presence and effects we have thus not become so accustomed.

Hippocrates defined consumption as the disease the most difficult to treat and that which proves fatal to the greatest number.

Isocrates, about 400 B. C., is said to have been the first to write on the transmissibility of consumption by contagion.

Aretæus, about 250 B. C., recommended sea-voyages for consumption.

Two hundred years later Aritæus, the Cappadocian, thus described the appearance of the consumptive: "Voice hoarse, neck slightly bent, nose sharp and tender; cheeks lean, prominent and red; eyes hollow, brilliant and glittering; swollen, pale or livid in the countenance, the slender part of the jaws resting on the teeth as if in smiling, otherwise a cadaverous aspect."

Celsus, early in the first century A. D., advised change of air and outdoor life for phthisis. Let us note in passing that Celsus was a layman who set forth the medical knowledge of his time and of whose encyclopedic writings those on medicine have alone come down to us.

Galen held that phthisis is an infectious process; that there is danger in living with those affected by it. Then came the long, dark night of the Middle Ages when learning, so far from advancing in Europe, fell into a decline, barely kept alive by the monks until the Renaissance. Even the monks, however, devoted themselves to the Latins rather than the Greeks, and were interested in theology and religion, scarcely at all in natural science.

The Arabs, however, revered and tended the lamp of science lighted by the Greeks, and passed it on to the Moors of Spain, and the influx of Byzantine scholars into Italy after the fall of Constantinople greatly stimulated the awakening interest in Greek thought in that peninsula, whence it spread northward.

Avicenna, the Arabian, in the first half of the eleventh century, believed consumption to be one of the diseases which spreads from man to man.

Six hundred years later, Fabricius Acquapendente writes, "Celsus amongst Latins, Paulus Æginetа amongst the Greeks and Albucasis amongst the Arabs form a triumvirate to whom I confess that I am under the greatest obligation."

Montani in 1550 called consumption one of the most contagious and easily contracted of diseases. With the Renaissance came dissection illuminating anatomy and pathology.

Silenius first demonstrated the association between tubercles or nodules in the lungs and phthisis.

Morgagni would not perform an autopsy on one

*The Shattuck Lecture, delivered before the Massachusetts Medical Society, June 11, 1907.

dead of tuberculosis, and was influential in having regulations passed by the municipal authorities to control the disease.

Antonio Cocci in the first half of the eighteenth century advised the use of sputum cups, and urged the whitewashing of all close, small rooms in which a consumptive had lived. If the room was large and sunny less rigorous measures were deemed necessary.

Lazarus Riverius dwelt on the contagiousness of phthisis and notes its spread throughout an entire family by heredity or contact.

Michel Peter, writing about 1600, says, "I know of nothing more hideously fetid than the bedroom of a rich consumptive. It is a spot carefully enclosed where both air and hope are alike forbidden to enter. There are sandbags to doors, sandbags to windows, thick curtains envelope the bed where the unfortunate consumptive swelters in perspiration, and an atmosphere twenty times respired, twenty times contaminated by contact with his own diseased lungs."

The Dauphin of France, only son of Louis XV. and father of Louis XVI., died in 1765 of consumption. About a year later his wife died of undoubted consumption as shown by the autopsy, probably contracted through her devotion to him. About two months before her death Tronchin, the favorite pupil of Boerhaave, the physician and friend of Voltaire, a man who applied common sense to medicine, relying on hygiene rather than on bleeding, purging and puking, was called in. In the palace at Versailles it was the custom to close as tightly as possible all windows from November first (All Saints' Day) to Easter. Tronchin found the air of the room so foul that he ordered the windows opened, exclaiming, "The princess is poisoned." Malice and jealousy perverted the meaning of this remark, which won him the implacable hatred of the Duc de Choiseul. Tronchin was put in charge of the case, fed her generously, insisted on fresh air, made her walk and drive. At first she improved, the fever abated, and she slept without drugs; but the disease was too far advanced, lighted up afresh, and she did not long survive a large hemoptysis. A storm of abuse was heaped upon him by the profession. He was called the "worst of charlatans," and was accused of cutting short the life of his august patient by a treatment "as fantastic as murderous." Tronchin is not as well known as he deserves to be, having published nothing on medicine except a monograph on lead colic, which might have been better done. A memoir of him by a descendant was published in 1906 and should be widely read.

In 1760 a hospital was erected at Olivuzza for the accommodation of phthisical patients. In much more recent times the Italians especially, their country being sought by well-to-do consumptives from Great Britain and America, were accused by us of superstitious cruelty towards these patients, the friends of one who there succumbed to this disease being put to great inconvenience and expense during the last illness and the freshness of their grief.

In 1803 Chateaubriand wrote from Rome to a friend concerning the death from consumption of Madame de Beaumont, "I am in great difficulty. I had hoped to get 2,000 crowns for my carriages, but phthisis is declared in Rome a contagious disease, and as Madame de Beaumont drove two or three times in my carriages, nobody is willing to buy them."

The great Laennec himself succumbed to the disease, the recognition and pathology of which he had done so much to further. There seems no doubt that Goethe also had consumption and finally died of it.

It may be broadly stated that until within fifty years both the public and the medical profession regarded phthisis as incurable. Efforts were practically confined toward making the patient comfortable and prolonging his life, in a small way toward preventing the spread of the disease, seldom toward curing it.

Early in the nineteenth century a French doctor, more hopeful than the rest, wrote, "There are two kinds of consumption: that of the rich which is sometimes, and that of the poor which is never, cured."

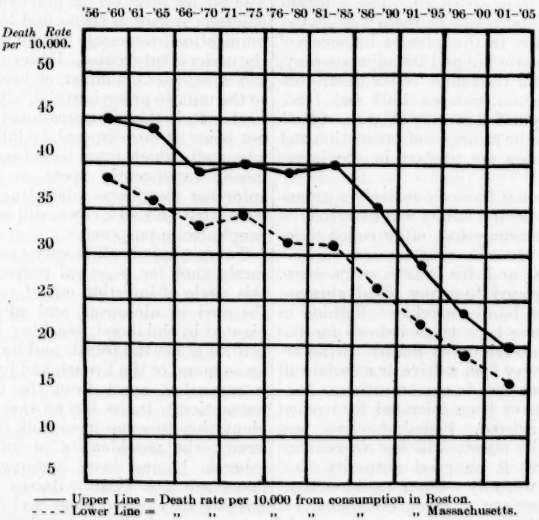
It is an interesting fact that the two men who stood at the head of medicine and surgery in this community during my student and early professional life had both been tubercular as young men; but both lived to the due age of the psalmist, and both died of other diseases. I was privileged to hear from the lips of the late Dr. Edward H. Clarke an account of a massive pulmonary hemorrhage he had between Bagdad and Damascus while traveling for the benefit of his health.

Very great importance was attached to hereditary predisposition, and, diagnosis being less prompt and treatment less rational, the outlook for recovery was indeed gloomy.

I well remember in 1874 hearing a French physician, with whom I was making a visit at the Hotel Dieu at Lyons, remark, "*Messieurs, pour la phthisie il n'y a que deux remèdes, l'opium et la menterie.*"

I also heard the late Dr. H. I. Bowditch say that he valued his service at the City Hospital especially for the reason that it helped and strengthened him to see patients get well under his care. You remember that he was the first and leading specialist of his time in Boston in thoracic disease.

Those who could afford to leave home went to Italy, Madeira, Egypt, the Riviera. On this side of the water, Havana, Savannah, Charleston were the main resorts. Dr. John T. Metcalfe during the Civil War gave Nassau vogue, and later started Thomasville, Ga. He was not a consumptive as have been so many physicians identified with this or that place which they found helpful to themselves and made so to others.



Did time permit it would be interesting to dwell somewhat on the change of view with regard to the essential element of climate for consumption. Warmth and equability to minimize the

risk of taking cold were in the ascendant up to about 1860. Then the equable though cold winter climate of Minnesota came into some vogue. Then equability fell from grace, and altitude combined with dryness and sunshine took the first place, especially for incipient cases. We now realize that climatic change, though in some cases very desirable, is not a *sine qua non* of cure.

Bowditch and Buchanan simultaneously and independently called attention to the relation of soil moisture to the prevalence of consumption, a relation now not much credited.

Some individuals were saved; some had their lives prolonged, yet the general hopelessness of the disease was admitted, though the post-mortem evidence of puckered and scarred apices had long been known but had failed to teach its full lesson.

CHART SHOWING DECREASE IN DEATHS FROM CONSUMPTION IN MASSACHUSETTS AND IN BOSTON.

It seems to me that ignorance of the pathology of tuberculosis was largely responsible for failure to advance at the clinical end. Laennec upheld the unity of tuberculosis; but the microscope led men astray at first, inducing them to confuse distinctions with differences. We had the desquamative pneumonia of Buhl, the catarrhal pneumonia of Niemeyer, and the dictum of the latter that the greatest danger of the catarrhal pneumonic, that is, consumptive, is that he become tubercular. We thus wandered in a maze of theory, based on observation it is true, but still theory, for years after Villemin in 1865 proved that the advocates of the infectiousness of tuberculosis were right, and made a step toward establishing the true criterion by which tuberculosis is to be recognized. For clinching knowledge as to this criterion we had to wait then nearly twenty years for Robert Koch and his masterly proof that a special bacillus is the sole cause of tuberculosis, and the indispensable factor in the production of all the multiform changes we had classed as consumption, lupus, scrofula, white swelling, hip and spine disease, etc.

The year 1882 marked a great era in medicine and may be regarded as dividing the past from the present of tuberculosis. We then for the first time began to see clearly, having found the cause, what we had to combat, and could begin to plan the intelligent campaign in which the civilized world is now engaged. The individual who was willing, bravely and cheerfully, to follow the directions of a wise physician and could also afford to do so, had a good chance fifty years ago, though in two respects particularly his chance has improved. His disease is recognized earlier, — a great thing in itself,— and his facilities for securing the prime *desiderata* for recovery are more varied and better.

A sharp contrast between the past and the present of tuberculosis lies in that good hope for recovery is extended from the exceptional to the average individual; in that we recognize and can minimize the danger of the spread of infection; in that knowing the cause of the disease and its mode of infection, by intelligent and concerted action we can prevent as well as cure. We knew that general hygiene was of the utmost value in the prevention and cure of tuberculosis just as we knew that stagnant water and defective drainage stood in some causative relation to malaria. The

discovery that an infected mosquito is the necessary link in the chain of causation of malaria enables us to act intelligently and efficiently, instead of gropingly and inefficiently, along preventive lines, our cure of the disease in the infected man being practically no better than it was before Laveran discovered the plasmodium malariæ.

Let us not forget that a tent on the roof, a shed open to the sun and fresh air in the backyard of a city house, camp-life in the woods, are not "all that there is of the most modern," as the French say.

As appears clearly in charted form, mortality from consumption was dropping gradually in this state from 1855 to 1885, since when the drop has been more steady and somewhat more rapid. It is interesting to compare the mortality in Boston with that in the state. From 1855 to 1865 it fell from 45 to 40 per ten thousand; then was stationary for twenty years, and since 1885 has steadily dropped from 40 to 20. The constant influx of immigrants, many of them vulnerable, and their subjection to the adverse influence of urban tenement-house life and its adjuncts may, perhaps, account for the failure of the death-rate to decrease in Boston between 1865 and 1885, while the more rapid fall in mortality since 1885 may well be due to the measures of prevention and cure which are more apt to start in the larger centers.

It is safe to say that formerly scarcely a prominent and wealthy Boston family was free from its case or cases of consumption, often called "decline."

A century ago, and for many years after, women were subjected to many disadvantages. Robust health was hardly ladylike. Fashion in custom and in dress kept them indoors far too much. Outdoor exercise was limited to horseback riding for a very few, a drive or a social call at short distance on foot in good weather. Athletics would not have been tolerated for women even if they had existed. Female footwear was not adapted to the street, still less to country roads, and I have it on good authority that drawers were not worn by women until less than one hundred years ago, it being considered indelicate to clothe that part of the person so nearly after the manner of men. One of the numerous daughters of a wealthy merchant, all of whom long held out against the introduction of drawers for women, was remonstrated with by one of her friends who remarked, "But suppose you should fall down in the street," to which she replied, "A *lady* does not fall down in the street." It is not in flippancy of spirit that I mention these facts. They seem to me to throw an interesting sidelight on the times, and to give a hint as to why practically none of the descendants of those families die of consumption at present. Now and then one gets the disease, but it is promptly recognized and almost invariably cured. It is, however, time to leave the past and to let the dead bury their dead.

Strengthened by and relying on modern knowledge, we are now engaged (I), in the prevention of tuberculosis in all its forms, and (II), the cure and care of those now infected by it.

I. As already stated, it is in prophylaxis especially that we have gained by Koch's discovery. A few words must therefore be said on the mode of infection. The seed is the bacillus of tuberculosis; it is virtually omnipresent in civilized and settled communities; it succumbs readily to sunshine. How long it may retain its vitality in houses, fabrics, etc., we do not know, perhaps not as long as is often and by many believed. Theobald Smith tells me he cannot keep a culture alive more than three months even under conditions most favorable to the longevity of the organism. To his published work and ready kindness in imparting his knowledge I may here express my indebtedness. We are all his debtors. The bacilli of human and bovine tuberculosis are separate organisms to-day even if they may have had long ago a common ancestor. The bovine form occurs practically only in young children, is rare in them, and the risk of its communication from cattle to man is very small unless the udder is tubercular. Under no other condition can a sufficient number of bacilli gain entrance to the milk to prove harmful. The meat is safe as food. It is therefore irrational, unlimited funds not being at our disposal, to kill all cattle, otherwise well, which react to tuberculin. Much less money intelligently spent in dairy inspection, enforcing cleanliness, detecting and eliminating emaciated and sick cows, will serve all necessary prophylactic purposes.

Tuberculosis itself is very rarely congenital, so rarely that for practical purposes we can leave this mode of infection out of account. Whether the seed of adolescent and adult tuberculosis is planted in childhood, reaching the blood stream and lungs *via* the tonsils and intestines, as is held by so many of the French and by Behring, or not, is somewhat apart from the broadest view of prevention. In so far as they believe the implantation to come from milk they are probably wrong, the non-identity of human and bovine tubercle having been apparently proved. All floors are not clean. Babies in crawling and walking are close to them, and like dogs they are not over particular as to what they put in their mouths. The seed lives in man and must be able to get from one man to another, to change its dwelling, in order to persist. Its vehicle is the sputum in the vast majority of cases. It is therefore by efforts tending to prevent the preservation and diffusion of the sputum of those affected that we can most simply and efficiently limit the supply of seed, which furnishes such a rich harvest to the Great Reaper. It is fortunate that a remedy which must be generally applied is so simple, — really within the reach of the lowest intelligence and the most slender purse. The community as a whole is rapidly learning its interest in the care of sputum. The individual is, probably less rapidly, awakening to his duty, first, as a member of a family; second, of the community. We must continue to diffuse this

knowledge and to enforce, as fast and far as we can, action in accordance with it.

The only way to absolutely eradicate tuberculosis lies in total destruction of the seed, a conceivable rather than an attainable possibility. It is notoriously a seed which flourishes on poor soil. Whether poor from the start — congenitally poor — run out in one or more of a thousand ways, or both together, matters little for practical purposes, save that the children of families with a strong tuberculous taint must be tended with extra care and wisdom. Therefore an important part of prophylaxis is to so enrich the soil, that is, to so increase the resistance of every member of the community, that such seeds as may gain lodgement will die without issue, or, at all events, without extension. Thus everything which tends to improve public health is helpful — cleanliness; good and sufficient food, well prepared; pure and ample water supplies; public parks and baths; children's playgrounds; legal restraints upon the greed and stimulation to the inertia which neglects the hygiene of tenements, workshops and factories; cultivation of a taste and provision for the means of outdoor exercise and recreation. These are far from being all, though they are among the most important agencies uplifting the public health. It is to them that the decreasing mortality from consumption up to 1885 is to be exclusively credited. Nothing like an accurate apportionment can be made of the relative value of seed destruction and soil enrichment since that date. Seed destruction is a new factor within twenty years; but during this same period we have seen ever-increasing attention to hygiene in all its branches, especially on the part of the state and the municipalities. The golf course and tennis courts in Franklin Park, the ocean pier at South Boston, public baths, the medical inspection of school children — imperfect as it is at present — these are straws which show the way the wind blows. Straws they are too in another sense, threatening to break the back of that patient camel, the city tax-payer, burdened with an extravagance — or worse — of expenditure, which no private business could or would tolerate. Quick transit tends to diminish the density of urban population. Corporations, partly under the pressure of public opinion and legal enactment, but also from the mingled motives of justice and self-interest, improve the conditions of their employees. Public-spirited and benevolent citizens are forming new organizations, and are also as individuals helping along the work. All indications point to great vitality in these influences making for the public weal. Individualism, the saving grace of fifty years ago, has been weighed in the balance and found wanting. Its antithesis, socialism, is advocated by some and feared by others, though the soil of the United States is probably less fitted for it than any other on the globe. The legal maxim, *caveat emptor*, is confronted by pure food and other laws limiting the freedom of the individual for the greater good of the community. The individual must be ready to forego privileges, some of them perhaps innocent as far as he alone is concerned. President Eliot well said in a recent address that it is in co-operation that we can attain the best results, and nowhere will co-operation enriched with public spirit yield a richer harvest than in, wisely and along broad lines, striving to prevent tuberculosis.

Among prophylactic measures, those of which Grancher may be regarded as the parent in France must be mentioned. In that country the belief is widely held by physicians that tuberculosis is usually contracted in infancy and childhood, even if it does not develop until adult life. Grancher and his wife started the movement to remove the children of tuberculous parents with their consent to country houses or sanatoria until the children are strong enough to resist the disease. It is claimed that 50% of those children are cured. There are only two such sanatoria on our greatly extended seacoast. Children with enlarged glands — tubercular — and those debilitated from any cause,— pre- or potentially tubercular — are followed up to their homes and either removed to "*écoles de plein air*" or built up at home by generous diet and instruction of the parents in general hygiene. It has been found far better to enlist the interest and intelligent co-operation of parents in better feeding than to furnish milk and eggs and the like at school. This work is growing rapidly and is in private hands, not, as is usually the case on the Continent, under governmental control or pay.

The proposed extension of medical inspection of the Boston school children and a detail of nurses to visit and teach the families could render great service along these lines, and may, it is hoped, spread widely and rapidly.

II. We now pass on to a brief consideration of the measures at present under trial for the cure and care of those not only infected but diseased. As Theobald Smith keenly observes, infection and disease are not quite one and the same thing. A person may be infected — harbor the bacilli of tuberculosis perhaps indefinitely — and yet remain perfectly well. He is not diseased, strictly speaking, until the infection spreads locally or generally.

Perhaps clearness may be promoted by the rough separation of the advanced and the early cases. I say rough advisedly, inasmuch as the best means to combat tuberculosis is a new subject, experimental, somewhat chaotic, rapidly developing. The leading principles are fairly clear; but we are to learn how to apply them to existing conditions in a decentralized country composed of forty odd sovereign states, presenting often wide divergencies in climate, industries and other important respects, not only between but also within each other.

Measures desirable in and applicable to Germany, for instance, may be entirely out of place in this country. It is in some regards easier to classify for the future than for the present.

Cure can be expected in very few of the advanced cases. In such we may aim at pro-

longation of life, promotion of comfort and the safety of others.

In the well-to-do the disease is usually recognized early and pretty well cared for at the present time. Among cleanly people with reasonably spacious, sunny and airy quarters, the risk of the spread of infection is very small. This appears clearly from the experience of the older hospitals and sanatoria for consumptives in Germany, England and this country. In such hospitals it is not common for attendants to acquire the disease, though Dr. James Minot tells me that six nurses have developed consumption at the Long Island Hospital since 1896. They all entered the training school with a physician's certificate of good health. He does not know whether or not they were examined soon after their arrival upon the Island. City politics are killing to body and soul alike.

Dr. Nichols, however, writes me that during the fifteen years he has been connected with the State Hospital at Tewksbury, one physician can reasonably, and two officers possibly, be supposed to have contracted the disease there. He also states that he has never had any evidence of the spread of the disease from one patient in the institution to another; and yet during the first half of this period segregation of consumptives was very incomplete, and those exposed, being paupers, were presumably not up to the average standard of resistance. Those who wish so to do can contrast here Boston and the state.

In the House of the Good Samaritan for over fifty years half the adult inmates have been consumptives, generally advanced cases, and no attempt at segregation was made until removal to the new building two years ago. During this half century, among all employees one nurse alone contracted the disease within the walls as far as is known. A good illustration of what can be done even under very unfavorable conditions is afforded by the so-called " lung block " in New York. It is in the most congested and crowded district in the world, the ward containing it averaging 78 human beings to the acre. This block alone holds nearly 4,000 people, of whom some 400 are babies. It is closely packed with huge grimy tenements which are honeycombed with rooms. Light and air have been slowly shut out to make more rooms. Walls, courts and air-shafts are cramped, deep and sunless. The body of the block is packed with Jews, Irish and Italians, with a sprinkling of twelve other nationalities. Owing to the comparative immunity to tuberculosis among the Jews there are relatively few cases of consumption in this block in their race. One house, called the " Ink Pot," has front and rear tenements five floors high with a foul, narrow court between. Here live 140 people of whom 23 are babies, and here the plague thrives in darkness and filth, — filth in the halls, over walls and floors, in sinks and closets. On the ground floor in one corner where there is apparently little sun and light lives a German family who have kept their windows opened and their rooms well-aired and spotlessly clean. They alone have escaped the disease. Practically every other tenement in the block has had its case of consumption.

It is of the utmost practical importance that the public should clearly understand that while tuberculosis is infectious its infectivity is slight, provided that simple precautions are taken.

Advanced cases, among those who, though not well-to-do, can still provide for themselves reasonably well and therefore usually stay at home, are a very important class to find, educate and follow up to see that they and those with whom they live practise what they are taught. Advanced cases among the very poor, who require so much personal attention, to say nothing of such food and hygiene as their families and friends cannot provide, are best cared for in hospitals, public and private.

At the State Hospital at Tewksbury, Dr. Nichols writes me under date of March 25, there are 247 cases of tuberculosis. In a special building and neighboring camps and shacks, half a mile from the main hospital, 160 men are cared for; but the cases have been sent in such numbers this winter that it has been necessary to put about 30 men in the earlier stages of the disease in the regular hospital wards. Dr. Nichols is asking the legislature for an addition for fifty patients to this building, merely to meet present and urgent demands. A building for female consumptives, also more than half a mile from the main buildings, will be ready for patients this spring. This is the only public state provision at the present time in Massachusetts confessedly for advanced cases; and to enhance its usefulness, the legislature a year ago so changed the law as to allow its benefits to consumptives without thus making them legal paupers. The Boston Hospital for advanced cases will be opened before long. There are a few private institutions solely for advanced consumption. There are others which receive such cases in common with other more or less incurable chronic diseases. The present provision is quite inadequate. It is true that less than one-third of the cases at the Rutland Hospital belong to the incipient class. Although it was for that class that the hospital was designed, not enough incipient cases apply to fill the beds, and more advanced cases are therefore taken. For this state of affairs the resident physician blames the medical profession in that it too often fails to make an early diagnosis. This blame is probably in the main deserved, though we all see patients who seek no medical advice until they have passed well beyond the incipient stage. The number of these cases will doubtless steadily diminish in the near future.

The present provision for less advanced and early cases in this state may be classed under:

1. Sanatoria.
2. Dispensaries.
3. Day camps.
4. Tuberculosis classes.

The sanatorium treatment dates back to 1854, Brehmer, of Goebersdorf, succeeding where Bodington had failed. The latter should be accorded

the tardy credit which he did not receive during his life. In 1840 he, " an obscure country practitioner of Warwickshire," published an essay on " The Cure of Pulmonary Consumption on Principles Natural, Rational and Successful," based on the case of a young girl whose faith in him prevailed against the most strenuous opposition of her people and who passed her days, even in winter, out of doors on donkeyback. Although at first her cough was worse, she persevered, recovered, and lived to be eighty-one years of age. He built an institution within which to carry out his ideas, but could not hold out against universal opposition and transformed it into an insane asylum where later he died — a tragic story. Time does not permit even a brief history of the sanatorium movement, but I cannot forbear to mention Dettweiler, Trudeau and Vincent Bowditch. The first sanatoria were private, and our state took the lead in public provision for early cases at Rutland. It will not be many years before every state has one or more such centers, the movement now spreading to cities and towns.

It is natural that provision should be first made for early, presumably curable, cases. " What can't be cured must be endured." We like to see prompt results. The educative value of sanatoria for incipient cases is at present great. Every inmate learns what the effective weapons are for fighting his disease and how to use them. After his discharge this knowledge filters more or less clearly through him to others who stay at home, and also teaches him, and through him others, how to live without risk to the well. We already see, however, indications of a spreading belief that the greater need is for hospitals to receive advanced cases with disabling and incurable disease, and whose circumstances are such that they cannot at home receive the care which ordinary humanity demands, or be safe companions for the healthy. The State[1] Commission on Tuberculosis has just recommended the legislature to establish three hospitals in different parts of the commonwealth for such cases. It does not advise any more provision for early cases. Institution life at best has serious disadvantages, particularly for those but partially or slightly disabled. Such degree of productive or useful occupation as strength permits is conducive to health. This is difficult to secure in connection with sanatorium life, and it has been suggested that some kind of farm work be an adjunct to Rutland for those who are fit.

This can only be carried out during a limited part of the year. An objection common to health resorts and sanatoria alike, whether for the rich or poor, lies in the congregation of considerable numbers of persons suffering from the same disease, and in tendencies to a mental state resulting therefrom. The person who stays at such a place longer than his disease and circumstances in a large sense really demand from that moment gets harm physical, mental or both. Here, as everywhere in medicine, we must individualize as far as we can, and we can often do so farther than seems possible if we will only compel ourselves to the hard work of thinking.

Such luxurious provision as is made in some of the German institutions is neither necessary nor desirable. It is sheer extravagance begotten of too much money, analogous to that of some of our life insurance companies which have been so cussed and discussed of late. Just as we have begun to see that climate is only an indirect means for the treatment of cases of tuberculosis; that there is no part of the world where the disease does not exist if favorable conditions are present or are introduced, great advance is made in home treatment, which must and should be the only treatment for the great majority of cases.

This brings us to the tubercular dispensary of which Philip, of Edinboro, was the founder in 1887. The Royal Victoria Dispensary was not only the first of its kind but is so complete to-day as to serve as a model.

The Edinboro organization aims to provide:

(1) A place where poor patients can be examined;

(2) Where bacteriological examinations can be made;

(3) For instruction of patients;

(4) Dispensary for drugs, disinfectants, food, etc.;

(5) Visits in homes of patients by
  (*a*) doctors;
  (*b*) nurses;

(6) Means for the selection of early cases for sanatoria and late cases for hospitals;

(7) For the general guidance of patients and their friends, to answer inquiries from all interested persons on every question concerning tuberculosis.

There are four doctors (one is paid $300 a year), a trained nurse, a volunteer Samaritan Committee of ladies who look after school children and families of patients. There is a paid employee on the premises who helps take histories, etc. The dispensary costs $2,500 a year. Interest has been awakened in other cities and towns. There is now a sanatorium for early and a hospital for advanced cases. To complete every such organization there should be colonies — or some means of keeping track of the after life of arrested or cured cases, and of getting them proper employment, etc.

Calmette at Lille in 1900 opened the Emile Roux Antituberculosis Dispensary. His idea has been taken up in Germany especially by Van Pütter and Kayserling, where numerous cities have opened so-called " Fürsorge-stellen," " Care and Advice Stations." Here instruction is given to patients who must live at home; sputum examinations are made, food and medicine are given when necessary, and visits are made in the homes of the patients themselves. In Boston in 1899 at the Boston Dispensary this idea was adopted. The Phipps Institution, opened in Philadelphia in 1903 through the generosity of Henry Phipps and under the guidance of Lau-

[1] Since this was written the legislature has adopted the recommendations of the commission and the Governor has appointed a commission to build these hospitals. State sanitary inspectors have also been appointed.

rence Flick, does this on a more thorough scale than almost anywhere else. In New York the Department of Health Clinic for the Treatment of Communicable Pulmonary Diseases, established in 1903, is the best example of such work under municipal authority.

Recently in Boston the system of tuberculosis classes has been introduced, and thanks to the enthusiasm and devotion of Drs. J. H. Pratt and J. B. Hawes, 2d, and Cleaveland Floyd, is bearing most promising fruit. This gives a large amount of care to a small number of patients, the reverse of what is done in most dispensaries. The "class" is a unit which can be indefinitely increased. Five such classes have been formed in Boston, two in New York, and one each in Cambridge, Providence, Brockton, Lynn and Baltimore.

Philip, of Edinboro, and Calmette, of Lille, are the two great names in dispensary work. Calmette's are called Preventoriums. Besides giving milk, eggs, etc., to poor patients, in some instances the rent is paid, it being considered a good investment.

Day camps originated in Berlin — "Walderholungsstätte," founded by Dr. Becher. Insurance companies pay for the food, and railroads give special rates to and from the camps, two cents for eight miles. These camps are for patients too advanced for sanatoria or who for some reason or other must live at home. There are two such in Boston, the only two in America. Berlin has three, the only ones in Europe.

The weapon against tuberculosis is education: education as to how it is spread, how prevented; how treated for cure and alleviation, and for safeguarding the community. The campaign is on. Earnest, devoted leaders have come forth from the profession, working with small thought of money return. The public is ready to help, to co-operate with brains, time, money, service. Are we doctors as a body doing our full share? I doubt it. Too many of us, I fear — I myself cannot plead not guilty — are more or less afflicted with inertia, congenital or acquired. There is a large supply of enthusiasm everywhere among the laity, which only needs the direction of physicians to bring new land under cultivation as well as to increase the yield of that already planted.

We cannot realize too strongly that everything which tends to elevate the public health, directly or indirectly, makes the struggle for existence of the tubercle bacillus harder. At one or another place in the world almost every necessary specific step for prevention or cure is taken. One place or country has given special attention to one branch of the work and gone far in it; another to another branch. Some places have done little; too many nothing. The work of the immediate future, therefore, would seem to lie in generalizing and systematizing the work in conformity with the varying modes of government and administration of each country and independent state, with due consideration of its customs, conditions, industries, etc. Modification of details must be made to meet the different demands of large cities, the factory town, the village and rural community. Just as good results can be secured where local self-government prevails as under a centralized and paternal system; but people must be made to see their importance and to desire them, securing proper legislation and ordinances, and providing means for the enforcement of the same. In our own state, the work for the immediate future would seem to lie in:

1. The passage of a general law making the reporting of consumption compulsory. But no such law can be thoroughly efficient unless the medical profession as a whole is competent to make an early diagnosis, and is in such sympathy with the law that the physician puts obedience to it and its underlying principle above the selfish preference of this or that patient and above any fear that he may lose practice by reporting him. It is not likely that such opposition will be very serious or long-lived.

2. Laws providing for the disinfection of dwellings occupied by the consumptive after moving or death.

3. An extension of the anti-spitting law, so as to include at least factories, mills, schools and the halls of tenement houses.

4. Legislative provision for state medical inspectors, responsible to the State Board of Health, each in charge of a district within which he supervises organized work.

5. Each community in the organization should have such force of nurses, visitors, or both as each may need; that the poor may be followed up in their homes, taught what to do, helped to do it, if necessary, and encouraged to persevere in doing it. Much of this can be done without, or with trifling, expense. There is much intelligent energy running to waste which can be turned in this direction.

All the above recommendations are made by the State Commission to investigate measures for the relief of consumption. Their report should be read and pondered by every physician.

Immense service can be rendered by arousing the interest of private and incorporated employers of labor in mills and factories. When the example set by the A. L. Joslin Company in this state and by the Sharpe and Brown Company and Mr. Metcalf in Providence at the instigation of Drs. E. P. Joslin and Fulton is generally followed, the mortality returns will tell the story, and there is no reason why it should not be followed if we physicians do our duty. Mill owners and managers are as a class intelligent and humane. Let their physicians call attention to this matter. It is highly probable that there will be no economic loss to the employer. There is more likely to be a gain to him, and the gain to individual workers, as well as the community, is sure to be great.

The tuberculosis exhibitions which have been held are potent aids in teaching the public the possibilities of prevention and cure. Such exhibitions should be brought within reach of the great majority of the inhabitants of the state. While the campaign is primarily against tuberculosis, success in its prosecution must indirectly diminish the liability to, or serious effects of,

many other diseases more or less intimately dependent on impaired vitality.

Past experience proves that the mortality from tuberculosis can be greatly reduced. There are those who go so far as to say that a systematic and energetic fight will render tuberculosis as rare as leprosy. Unless a vaccine comparable to that for smallpox, or some other means producing artificial immunity, can be discovered and universally applied, the above view would seem too sanguine. The problem of leprosy was a relatively simple one. That disease is far more difficult to transmit from one individual to another than is tuberculosis. Its lesions are mainly external and it is thus more easily recognized. The segregation of leprosy carried out during the Middle Ages could thus yield results hardly to be hoped for in the case of tuberculosis, an adverse factor in the attempt to stamp out which lies in that, unlike most of the more acute infections, it can be carried and perpetuated by a number of domesticated animals — cats, dogs, rabbits. The tubercle bacillus is being put on the defensive and we can be sure will fight for his life just as we are fighting for ours. Is it not possible that more resistant and virulent strains may develop, if not wholly, at all events partly, in proportion as we develop immunity? That nature is very careful of the species while seemingly regardless of the individual is as true of a bacillus as of larger organisms. Man has totally exterminated the great auk. The Labrador duck has utterly disappeared since 1860 without any assignable cause. The bison and the wild pigeon have practically disappeared. Animals which breed slowly, are defenseless, and, like the bison, require vast tracts of land coveted by civilized man, are handicapped in the struggle for existence. I am told that the few herds of bison which are preserved only just about hold their own, showing very slight, if any, tendency to increase. The balance of nature is very complex and may be very delicate. It does not seem probable that the disappearance of the wild pigeon, such enormous flocks of which still existed easily within the memory of many of us, can be attributed save in subordinate part to their slaughter by man. The part played by man in the extinction of the bison is probably larger than in the case of the pigeon. The preserved herds of bison are well cared for but can no longer migrate. Why do not they increase under protection as do moose and the white-tailed deer? Is it not possible that these beings had about reached their limit of adjustment to external conditions and that any slight change in the balance against them was too much for them? Our lives, and even the written records of man, are so short, and it is so hard for us, busy with our daily struggles, to project our thought and imagination far enough backward or forward. Man himself is a mere babe in arms in comparison with life on this planet, and his parasites in their present form must be younger still. The destructive moths which have caused so much trouble in these parts of late years find no adequate natural enemies in this country. In Europe they ordinarily are kept within bounds, but even there they now and then get ahead of their enemies for a time by reason of some change in the balance.

This line of thought may not be practical. It certainly does not materially influence action now or in the immediate future, but is seems to me deeply interesting and wholly pertinent to our subject of the evening. There is no tendency to race suicide in the tubercle bacillus. He finds an acceptable *habitat* in man, whose numbers are increasing and whose tendency in civilized countries to form large communities runs directly counter to some of the measures which he takes to protect himself against the bacillus. We know that we are decreasing and can further diminish the mortality of tuberculosis. Can we correspondingly decrease the morbidity? I doubt it. Tuberculosis seems likely to persist for a long time to come, perhaps indefinitely, in latent, more superficial, milder and more chronic forms. There can be no question that there are many persons — in all probability there are some such in this very room — who have or have had tuberculosis, even of the lungs, and who tolerate or have recovered from it without knowing that they have or have had it. Here again comes in the distinction of Theobald Smith between infection and disease. It is mainly to his suggestion that I owe the above line of thought.

If the master-word in medicine is work, that in the tuberculosis fight is education. Every teacher knows this to involve work — hard work. To paraphrase Talleyrand's definition of the main requirement of the diplomatist we can say, "*De l'éducation, encore de l'éducation, toujours de l'éducation.*"

The effort to compress so large a subject into reasonable limits has not been an altogether easy one. I trust that my sins of omission and commission may not be as obvious to you as they are to me.

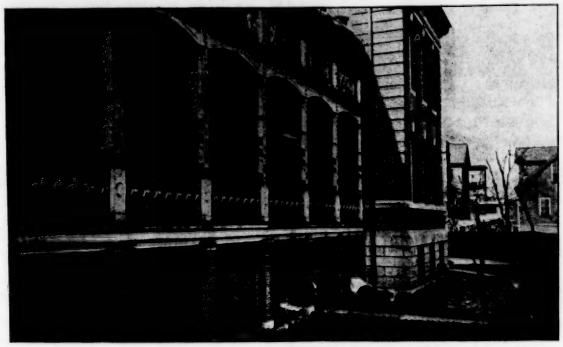
THE DAILY CARE OF CONSUMPTIVES AT A GENERAL HOSPITAL AS AN AID TO SOLVING LOCAL TUBERCULOSIS PROBLEMS.*



BY ARTHUR K. STONE, M.D., AND CLEAVELAND FLOYD, M.D., BOSTON.

In January, 1905, Dr. E. P. Joslin and myself, in our annual report, made the following recommendation to the Board of Managers of the House of the Good Samaritan who were expecting in the near future to build a new hospital building:

"It is hoped that means will be found whereby women and children will be encouraged to come to the House of the Good Samaritan and spend the day in the open air, receiving a mid-day meal, encouragement and advice, and return to their homes late in the afternoon in time to prepare the evening meal."

At this time neither Dr. Joslin nor myself had any knowledge of a somewhat similar experiment

Protection from the high winds.

The Camp in winter.

The Camp from the Samaritan Hospital. Harvard Medical School Buildings in the background.

being tried in the day camps for tuberculosis in Berlin. From long experience in out-patient work at the Massachusetts General Hospital and the Boston City Hospital, we had become dissatisfied with the inadequacy of such treatment as could be offered many ambulatory patients, and I had already urged upon the administration of the Massachusetts General Hospital the development of a roof garden, that should be conducted along lines similar to those outlined above. As yet the necessary funds to carry out these plans have not been forthcoming.

May, 1906, the managers of the House of the Good Samaritan undertook the experiment suggested in the above recommendation and appointed Dr. Cleaveland Floyd to have charge of the out-patients under the direction of the medical staff. It is the story of the year's work at the House of the Good Samaritan which I wish to present to you.

Before beginning upon the detail of the work I will say a word as to the hospital. The House of the Good Samaritan is an endowed institution, managed by a board of trustees, who are largely made up of the personal friends and relatives of the founder, Miss Anne S. Robbins, who devoted her long life to the management of the institution, living and dying within its walls. Her example and enthusiasm are shared by those who now carry on the work. The new building is the first of the group of hospitals which will eventually surround the beautiful new buildings of the Harvard Medical School. There is about an acre of land around the House of the Good Samaritan. The hospital was open to patients more than a year before the opening of the new medical school buildings, and daily clinics were held there. There are accommodations for about 43 patients. Twelve beds are devoted to children's orthopedic cases. The remainder of the beds are divided between cases of advanced phthisis and general chronic conditions. The House of the Good Samaritan is in no sense a " home " but a hospital for the treatment of chronic disorders. The members of the medical staff make daily visits. There is a teaching laboratory and a graduate house-officer in attendance, a Baruch hydrotherapeutic apparatus is in process of installation, and the solarium and balconies provide an abundance of fresh air.

The wards for the tuberculous patients and the non-tuberculous are separated from each other by single rooms, dining-rooms, bathrooms, etc., so that there is no contact between the two groups. Those who are able, however, eat in the same room, but at different tables and have china of different colors. The china of the tuberculous patients is cleansed and sterilized by boiling in an entirely separate room from the general serving-room where the dishes of the non-tuberculous patients are washed.

In passing I may add that, so far as is known, during over forty-six years of the hospital's history, but a single case of tuberculosis has been acquired by any of the hospital staff; many of the servants have been with the institution over twenty years, and a number of matrons and nurses ten to fifteen years.

The active attention to the care and treatment of advanced cases yields as great satisfaction as do the cases reported by Dr. Bonney last year. Cases are arrested and all traces of bacilli disappear; some improve so much that the State Sanatorium at Rutland is ready to receive them, and others go to pleasant country surroundings among friends. Even those who do not recover, nevertheless amply repay the care that is bestowed upon them by the way in which they respond to treatment, so that their last days are days of comparative comfort.

The nurses employed in the wards are all graduate nurses. They are under the direction of the superintendent and her assistant, both graduates of the Boston City Hospital Training School. There are, including two night nurses, ten nurses to look after the patients and the operating room, etc., the expense for salaries and wages alone being $7,479.48 a year.

The heat, light and power are furnished by the power plant of the Harvard Medical School, which is designed to furnish similar service to all the other hospitals and buildings which shall be attracted toward this medical center.

The expense of running the hospital amounted last year to $10.79 per week for each patient, which is, of course, a large sum, as the care for such cases is usually computed; but considering the care and attention and food that the patients receive, the cost is very moderate indeed.

After the new hospital had been in satisfactory running order for the space of six months the medical staff renewed their suggestion that an " out-patient " department should be started. They now had the experience that had been acquired by the successful operation during the previous summer of the day camp conducted by the Boston Society for the Relief and Control of Tuberculosis. It seemed to Dr. Joslin and myself that the expensive plant which was in fine running order could extend its sphere of usefulness greatly at a very small additional cost. The managers generously agreed to try the experiment, even though it necessitated some alterations in the new building to arrange for a dining-room for the out-patients and a separate sink at which their dishes could be washed.

A portable house was purchased which was put up on the south side of the main building and away from the street. This is screened thoroughly on three sides and can be used if the mosquitoes are too thick for comfort or in case of a sudden shower or hard storm. But for the most part it serves as a store-house for chairs and blankets, books and clothes, rather than as a sitting-room. In the stormy days of winter, in case of disagreeable winds, the patients sit upon a cement platform beneath the balcony of the main building, where they are protected on three sides from the weather but having fresh air and sunshine from the open southern exposure. Here there is room for 25 steamer chairs in a row. Whenever

the weather is at all suitable, however, the patients bring their chairs into the open and away from the buildings. During the hot days of the summer the patients move to the eastern end of the building for the sake of the shade. Harvard College has also kindly given the use of some unoccupied ground immediately behind the main building of the hospital on which there are some trees. This is very helpful, as in the summer there is an uneasiness among the patients caused by the heat that can only be alleviated by the possibility of a change in location. In the colder months the patients are contented to stay perfectly quiet in their chairs.

In May, 1906, Dr. Floyd started his day camp limited in numbers to 10 patients. The managers soon allowed him to increase his number to 15, and finding that the expense was not going to be overwhelming, in August allowed him to increase to 25. This is practically the whole number that can be accommodated on the grounds and in the dining-room or can be cared for effectively by a single nurse. It will be seen that by August, 1906, the capacity of the hospital for good had been increased over 60%, as we shall see later, at a very small additional cost.

The regimen of the patients is as follows:

At about 9 A.M. they begin to assemble, coming from their homes in electric cars if they do not live within short walking distance. The nurse is on hand to receive them and hear the report of the night and of affairs at home. She takes and records their temperatures, and helps them, if necessary, with their chairs, wraps, etc. A little after 10 o'clock they go to their dining-room where they have all the bread and milk they can eat, and in many instances it is fully 30 to 40 oz. of milk and several slices of bread. Eggs are added to this lunch in less rather than in greater amount according to the time of year and their expense. They then return to their chairs and remain quietly until 12.30, when they re-assemble for their dinner, which is the regular house dinner, meat or fish, potatoes and another vegetable, and some light pudding, with milk and bread and butter. In some cases an ounce of cotton seed or olive oil is added. For some reason or other the patients cannot be made to enthuse over cotton-seed oil, which others seem to have no trouble in administering to their patients.

Again the patients return to their wraps and chairs or the grass and shade of the trees. Two hours after dinner is a quiet time and no talking is allowed so that any may sleep that wish to do so. At 4 P.M. they are again assembled for another lunch of bread and butter and milk, and between five and six, according to the time of year, they return to their homes.

It is expected that all the patients, in addition to the food received at the hospital, have a breakfast and supper at home, and for the most part this is done; some, however, we fear, get very little besides what they receive from us.

The nurse is on duty all through the day and oversees the patients at their meals, takes note of those who are not eating well — and later interviews such to see what is the cause. It is part of her business to gain the confidence of the patients, so that they will tell her of their home worries, of their financial difficulties, about their husbands, children or lovers, as the case may be. At the weighing time, which comes for each patient once a week, the nurse is able to inspect the garments of the patients — for they are undressed and weighed in a sheet — and make sure that they are properly clothed. She sees that all who have not bathing facilities at home are tubbed and scrubbed at least once a week. Further they are taught cleanliness of person, and care and protection of those about them, and especially care of their mouths when coughing. Each patient carries on her arm a blue linen bag containing, within, a smaller waterproof bag, and also some sheets of tissue paper, which are used to protect the mouth when coughing, to receive the sputum, which is then placed within the waterproof bag. The papers containing the expectoration are burned each night, and the inner bags are washed in carbolic from time to time. This form of bag has been devised because few women have pockets in which a paper bag can be carried, and it has been found that they will not carry about a paper bag in their hands.

On Sundays the patients remain with their friends and families, and the nurse makes visits to the homes, sees where the patients live and sleep, sees the family who are there assembled, and is therefore able to make a report to the physician as to the home conditions. This inspection of the home and families is of great importance. Sometimes it is repeated on successive Sundays until conditions are made satisfactory, sometimes the conditions are so good that no further visits are necessary. But it is expected that a visit shall be made on every one about once in six weeks after the routine has been established. It goes without saying that this visiting requires tact on the part of the nurse, and not every one, no matter how skillful in the wards in the care of the sick, has the ability to gain the confidence of the patient and become her friend and that of the family as well. As the result of her visit or visits the nurse fills out a report which is filed in the records.

The physician calls each day, hears the report of the nurse, talks to the patients, and makes physical examination of one or more as the case may be, so that there shall be proper records of each case and that he shall have personal knowledge of the pulmonary changes from week to week. Practically all the medication is in the form of rest, food and fresh air. Heroin or codein is used if the cough is distressing, though in small quantities. Tuberculin is used in a number of cases both for diagnosis and for treatment.

The total number of patients treated since we started has been 71, and these have been given 5,900 days of treatment. These patients would be classified as follows: 1st, incipient, 8; 2d, well marked, 29; 3d, advanced, 34.

Of these there have been discharged: Arrested,

10; improved, 4, who went to Rutland, as home surroundings were unfavorable; relieved, 2 non-tuberculous, showing signs of consolidation, but proved to be chronic influenza by sputum and negative tuberculin test; unrelieved, 30, of whom 6 had died; under treatment, 25.

The 10 discharged arrested were under treatment for periods of time varying from three to eight months. Of these 10, only one was from the group of incipient cases and the others from the well-marked group. Since discharge these patients have been required to report to the Samaritan at least once every two weeks in order that there should be no undiscovered relapse. All are doing well and are steadily gaining in weight. Some of them have returned, unfortunately, to their former employment where the disease was contracted, four are taking complete care of their homes and one or two have returned to school or are remaining at home. Of the four improved cases who left us for Rutland two are doing well. One of these was from the incipient and the others from the well-marked class.

Of the cases unrelieved, 7 went to other hospitals, 3 went to Europe having shown no special change, 5 were discharged for insubordination, 5 gave up treatment in from one to six days, and 4 were unable to keep up. The 6 cases who died were all very advanced on admission and the prolongation and comfort of life was all that could be hoped for. Of the 25 cases under treatment at present, all but two advanced cases are doing well and it is expected that 4 will be discharged arrested before the middle of June.

A few striking cases are worthy of mention. A girl of twenty-two years from a poor home and surroundings about four miles from the camp, had well-marked involvement of both apices. The cough was distressing, and expectoration about 3 oz. daily. She began treatment ten months ago, steadily gained weight from the start, and with the constitutional improvement the process rapidly became quiescent. She gained 30 lbs. in six months, her lungs became entirely dry and she was discharged three months ago without a symptom and has remained well since.

A woman of forty years, showing an advanced process involving both lungs, with occasional night sweats and considerable expectoration came under treatment in December, 1906. She could not speak aloud on account of a larynx showing marked swelling and infiltration about arytenoids and false cords. She has gained 27 lbs., her cough consists of a slight attack every morning, her lungs are quiescent, and her voice has almost completely returned. A few weeks will probably add her to our list of arrested cases.

A woman of about twenty-eight years with a cavity in the left upper chest and extensive involvement of the right, after six months' treatment has gained 20 lbs., the general condition shows remarkable improvement, the lungs are rapidly drying up and we hope for cavity contraction.

Complications and emergencies have been very few in number. There have been no severe hemorrhages on the grounds, and only one patient when at home has had two moderately severe hemorrhages, of about one-half pint of blood each time. One other patient had a slight hemorrhage. Even chills are of rare occurrence, and no cases of pneumo-thorax have occurred. Diarrhea in the summer months and grippe in winter have been the greatest enemies, and while all have been retarded at times by these ailments, only one or two have been seriously affected.

One patient who had an advanced process with a quiescent tuberculous larynx, after five months of treatment gained 20 lbs., cough was dry and the lungs were almost free from râles. The patient caught a severe cold and the quiescent throat flared up. Swallowing became impossible from pain and she died in about four weeks, practically from starvation as the lungs remained quiet. She refused to enter a hospital.

High temperature is not of frequent occurrence, and when it persists the case is required to remain at home for a few days in bed, being visited by the nurse in the meantime until the patient is thought fit to report for treatment. Pregnancy has only complicated conditions in one case and here improvement has been so constant and marked that we hope to escape the almost certain usual termination of this disease following confinement.

Tuberculin has been in constant use both for diagnosis and treatment. We are giving Koch tuberculin T. R. (imported) in about 15 cases once or twice a week. We begin with a dose of .0001 mg. and steadily increase it, avoiding reactions until we reach 1 mg. The arrested cases receive tuberculin weekly when they report. This treatment is only given to selected cases where cavity, fever and hemorrhage are absent. We feel confident that this has benefited not a few cases in quieting tubercular laryngitis and stimulating resistance in cases that improved to a certain point and then remained at a standstill. We have been more ready to allow an arrested case to return to her former employment because fortified with increased resistance by this means.

All the cases are proved to be tubercular by finding tubercle bacilli in the sputum or by the tuberculin reaction. In several cases this latter test has been necessary, and here Koch's old tuberculin in successive doses of .1 to 1 and 10 mg. has been used at intervals of four days. In only two cases have we failed to get a positive reaction where it was required for diagnosis, and these have proved to be cases of chronic influenza.

Our experience has demonstrated that in the climate of Boston an open-air camp can be conducted successfully both winter and summer, spring and fall, — cold and wet and disagreeable days appear to have but little effect upon the attendance. The results of the experiment have been very satisfactory from the clinical side, and it seems that the treatment presents these distinct advantages.

The daily removal from their homes gives the patients a decided mental shake-up. They have the companionship of others, some of whom are

worse off than themselves, they are distinctly doing something to make themselves well — taking the cure in the fresh air — and they are free for the time from the depressing influences and petty annoyances of home environment. The constant presence of the nurse in whom they can confide and talk over their family difficulties is of great assistance, and, at the same time, she deters them from conversation about their symptoms. The daily visits of the doctor, to whom trivial, but to the patient important and perplexing, questions can be referred, all tend to keep up the general morale of the patients. The responsibility for their own actual condition is shifted to the shoulders of the nurse and doctor and not carried in doubt by themselves. On the other hand, the constant supervision of the nurse enables the detection of unfavorable symptoms to be made early, as well as wrong-doing and recklessness. With the wards of the hospital always at hand to help out in cases of emergency, such as the appearance of a sudden rise of temperature, hemorrhage or other unexpected event, there is a sense of security not otherwise felt.

To those who still believe that temperature taking and the daily booking of symptoms are not desirable things for the majority of patients to do, this form of treatment must appeal; while those who think that it is a desirable feature in treatment can add it to the régime.

Many patients cannot be removed from home, and have even a small sum paid for their board without great discomfort to the whole family. In order that the mother may go to a sanatorium often the children have to be put away in "homes" or boarded. By our method the home is kept intact and as soon as possible the patient allowed to participate in the light home work during the mornings and evenings, often to the great advantage of all concerned. The daily education at the hospital is carried back to the homes with the result, we believe, that the other members of the family will lead a much more hygienic life than they otherwise would. The one disadvantage that we can see is that connected with the going to and coming from the hospital. There is necessarily a certain amount of wear and tear upon the patients during this time that is undesirable. To obviate this we are trying to have our patients, as far as possible, from the district immediately about the hospital. When this is accomplished, as it will be in the course of time, the House of the Good Samaritan will become a center for this particular portion of the city; and the ease of administration on the part of the nurse, and the one disadvantage to be urged against the scheme, will be reduced to a minimum.

As to discipline there is very little to say. There are so many applicants that if patients are neglectful and do not come regularly and punctually they are warned that if they persist they will be dropped from the rolls and their places filled by others. Naturally there are a number who come who do not like the restraint and discipline and quickly give up. Some are soon found to be too weak really to undertake the daily journey, but beg to be allowed to try and in a short time have to remain at their homes or enter other institutions for care and treatment. Most of the cases are, however, selected from patients presenting themselves at the general medical clinic of the Massachusetts General Hospital, where Dr. Floyd is also on duty, and it is here that he is able to make his selection of patients living in the vicinity of the hospital.

Incidentally, I may say that our experiment has aroused no interest among the doctors in the vicinity. When we started our experiment we invited all the doctors of the neighborhood to a tea at the hospital to explain to them our purpose and ask their co-operation, but no one came excepting one or two who were specially identified with the tuberculosis crusade, and had no need to be present, knowing well all about the work beforehand.

At the end of the year it is well to look over our books and consider whether in reality the experiment has been an economic success.

The first cost of the undertaking was defrayed by special gift to the hospital for this purpose, and nearly $1,000 was spent. With this money the portable house outside was purchased and set up for $324, and the necessary changes in hospital were made, to provide a new dining-room for the hospital help, and to provide water installation for separate dish-washing in the old dining-room that was to be used by the out-patients. Fencing and grading had to be done. In addition, chairs, blankets, comforters and hot-water bottles had to be purchased. These latter are not expensive and can be used for some time without renewal. These changes are in the way of permanent investment, and should not therefore be put into the general cost of maintenance, for the necessary changes in any other hospital would be entirely different and would depend on the local conditions. The cost of blankets, chairs, etc., depends on the quality. We have used the Allen camp chair, costing $1.75. It is light, easily handled and comfortable. Gray blankets have cost $4 per pair. Comforters are also useful in the winter and cost less than $1. Stone water bottles costing about 25 cents apiece are used, as they keep the heat longer than rubber ones, and do not leak as easily.

At the beginning of the experiment it was not found necessary to employ a special nurse for this service, but as the numbers increased the whole time of one nurse has been required. An additional maid was employed from the first to care for the dishes in the dining-room and assist the cook to serve the meals. These have been the only additions to the administrative staff of the hospital that has been required to care for the 25 patients. The remainder of the expense has been for their food. It is impossible to estimate exactly the cost of this food as a certain part is bought with the general supplies of the hospital — milk, butter, eggs and flour, the principal items, can be told exactly, but vegetables, meats, etc., can only be approximately estimated by comparison with the previous monthly expenses of the hospital.

Milk costs a trifle less than 7 cents per quart. Eggs vary from 50 to 20 cents, and are used accordingly. Butter costs on the average 28 cents. Flour has been $5.50 to $6.00 per barrel. The total cost of the experiment for extra service and food for the year has amounted to rather less than $2,000. For this amount there have been given 5,900 days' treatment, making a cost of 33 cents per day for each patient.

In the beginning, when there were only 6 to 10 patients, the actual cost of the total hospital expenses was less than it had been during the preceding year when the hospital was first opened. This was due to economies that had been introduced during the year. This is only mentioned as it was a great encouragement to the managers to find that the hospital bills rather decreased than increased during the trial period of expansion.

In conclusion, all that remains to be said is that the House of the Good Samaritan has apparently made an experiment which can be adopted by many communities to assist them in solving their local tuberculosis problem. Many towns and cities have small hospitals whose beds cannot from the nature of things be used to care for the cases of tuberculosis of the town or city. In the smaller places practically all the physicians are interested in these hospitals and therefore can co-operate in having a large portion of tuberculous patients who come under their care congregate at the hospital. This real knowledge of the patients and their home surroundings by the physicians themselves is an advantage that the physician of the large city does not possess and for the most part has to learn second-hand through the eyes of his visiting nurse. It is perfectly possible for ways to be devised so that each patient shall return to his or her own physician for treatment or advice, or the work can be delegated to a visiting man, as may be deemed wisest. Those who support the hospital by their contributions can be educated to the need of such a day-sanatorium by lectures and the organization of a committee on tuberculosis and thus still greater interest in the hospital aroused in the community. Such patients as can should pay a small fee for their care at the hospital. It may be possible later either to get a special pavilion built for the care of the very advanced cases of tuberculosis or to get the city authorities to take action and provide beds to which the stigma of pauper is not attached for this much-deserving class of sufferers. To the community having a hospital in active operation that will attempt to follow this experiment we feel that more can be done to help the sufferers from phthisis and at a much less relative cost and trouble than by any other means yet suggested to fight tuberculosis.

Mrs. Russell Sage has given $125,000 to the Association for the Relief of Respectable Aged Indigent Females in the City of New York. The home of the Association, at 104th Street and Amsterdam Avenue, is being extensively enlarged, and when the addition is completed its capacity will be increased from 90 to 270 beds. — *Medical Record.*

ON NEUROLOGICAL AND PSYCHIATRIC DIAGNOSIS.*

BY LEWELLYS F. BARKER, M.D., BALTIMORE.

On taking up the subject allotted to me, "The Historical Development and Relative Value of Laboratory and Clinical Methods in Diagnosis, with Especial Reference to Neurological and Psychiatric Diagnosis," I must confess to have experienced some difficulty in deciding how to treat it. It was not entirely clear to me how sharply to separate clinical from laboratory methods.

If one means by a clinical method a procedure which is carried out at the bedside of the patient and by a laboratory method one which is applied in a room, building or workshop, especially fitted with suitable apparatus for conducting investigations in diagnosis, he is making a distinction where there is not always a difference, for the bedroom, at any rate in hospitals, is a room so fitted and is a laboratory. If by laboratory methods are meant those which cannot be applied at the bedside, then we have relatively few laboratory methods of diagnosis in neurology and psychiatry, though the recent development of biological reactions and complex metabolic studies give promise of more in the near future. Most physical, chemical and psychological methods of diagnosis can be used at the bedside, though it is not always convenient to use them there. Or if by laboratory methods we mean methods which are generally or more conveniently used in special rooms not occupied as the bed-room of the patient, then the field of laboratory diagnosis is wider, especially if instead of limiting the examinations in these rooms to the study of materials removed from the patient we take the patient himself there, as we often do, for the making of certain tests. But if the patient himself is removed to the laboratory for examination, the physician is at his side, and the method remains clinical. Thus it is obvious that bed-rooms are used as laboratories, and that laboratories are used for clinical work, and no sharp line can be drawn between the work and methods of the two places.

Nor is it feasible to distinguish clinical methods as methods of simple observation from laboratory methods as methods of experiment. For we make relatively few observations that are simple, unaided registrations of sense-impressions. On the contrary, the great mass of so-called clinical observations are observations under particular conditions modified at the will of the observer; that is to say, are experiments. Moreover, in all our clinical work — in the collection of facts, in the arranging of them, and in drawing inferences from them — the results of researches in laboratories are continually being utilized. Our observations, our arrangements of facts in sequence, and our conclusions are practically all based upon knowledge which at one time or another has been gained in special laboratories.

Thus while there are clinical methods in neu-

* Read before the Congress of American Physicians and Surgeons in Washington, May, 1907.

rology and psychiatry that are not laboratory methods, and there are laboratory methods which can only remotely be regarded as clinical, it seems to me that all the methods used in neurological and psychiatric diagnosis must be regarded as clinical methods whether they are applied at the bedside or in any one of many clinical laboratories. My task is therefore made easier and it will be permissible, perhaps, to devote all the time at my disposal to a brief consideration of the way in which neurological and psychiatric methods of diagnosis developed to their present status. No hard and fast line can be drawn between laboratory and clinical diagnosis.

The clinic is the mother of the medical laboratories, and they have one and all since their birth contributed to the parental support. The anatomical laboratory dates back three hundred years. The physiological and physiological-chemical laboratories, the pathological laboratory, the pharmacological laboratory and the hygienic laboratory were creations of the nineteenth century. The first general clinical laboratory proper for internal medicine was established by von Ziemmsen a little over twenty years ago.[1] The facilities now offered in well-equipped laboratories in connection with hospitals, manned by trained observers, are of incalculable value, bettering as they do the diagnosis, the prognosis and the treatment for the patients, besides serving for the promotion of knowledge. The recent division of the research work of the general clinical laboratory into biological, physical and chemical sub-departments marks another era in medical-laboratory specialization. The foundation of the electro-diagnostic and electro-therapeutic laboratory was a landmark in the history of clinical neurology, and the establishment of psychopathic laboratories, beginning with that set up by Kraepelin (1894), promises to be of fundamental significance for the advance of psychiatric diagnosis.

The diagnosis of nervous and mental diseases made but slow progress until comparatively recent times. Mere clinical observation unaided could do but little until (1) laboratory studies had supplied some preliminary knowledge of the structure and functions of the nervous tissues; and (2) the growth of psychology as a science had yielded some insight into the workings of the normal mind. Physicians had from early times on recorded a number of symptom-complexes, and pathologists had observed certain of the grosser lesions in the central nervous system, but a knowledge of the relation of symptoms to lesions grew far more slowly in neurology than in other departments of internal medicine. The reasons are not far to seek.[2] The mere mechanical difficulty of opening the skull and spine was an impediment to neuropathology. Further, owing to the chronic course of most diseases, those who observed the early symptoms rarely followed the cases to their termination, and in homes for the incurable and asylums where the late stages were passed through, there was too often lack of medical interest. The peculiar and complex structural organization of the nervous system was appalling to the majority of investigators. It was easier to study the pathology of diseases of the lung or liver, in which alterations in one area produced effects similar to those in another area of the same size, than to investigate the central nervous organs in which apparatus ministering to totally different functions may lie close together, perhaps only a few millimeters or a few centimeters apart, or in connection with which the disconcerting observation had been made that a lesion the size of a pin prick in one area can be of greater injury to the organism as a whole than the passage of a crowbar through another. In a whole series of diseases, manifestly of the nervous system, no anatomical changes were discoverable on thorough miscroscopic study of serial sections of the organs. It is but little wonder that the majority of physicians have preferred to work at problems which seemed easier to solve than those which the neurological and psychiatric inquirer is compelled to face.

Fortunately for the sciences of neurology and psychiatry, however, there have always been minds to which these problems have particularly appealed, and to which the difficulties, though great, did not appear insuperable. Romberg, inspired by Sir Charles Bell's great discovery of the sensory and motor nerves, and influenced by the more precise researches of Magendie, realized the value of applying physiological knowledge to the study of neuropathology and to neurological diagnosis; he gave modern clinical neurology a firm foundation by developing knowledge concerning disease of the peripheral nerves. In psychiatry, after Pinel had broken the chains in the Bicêtre, and John Conolly at Hanwell had promulgated the doctrine of " no restraint," a great step forward was taken when Griesinger made it clear that the science is a part of neuropathology and inseparable from it, and showed how necessary a thorough knowledge of the latter is for scientific work in the former. Griesinger's recognition of the defects in medical teaching of neural and mental phenomena and his demand not only for theoretical instruction, but for practical work by students in psychiatric clinics to be established at the universities, led first to the foundation of special clinics, and many years later to obligatory attendance and obligatory examinations in these subjects. These reforms gave an enormous impetus to the advance of both diagnosis and treatment in neurology and psychiatry.

Modern neurological diagnosis is a direct outgrowth of the physiological research undertaken on the nervous system at about the middle of the last century. The studies of the electrophysiology of muscles and nerves, the recognition of the spinal cord as an organ more or less independent of the rest of the nervous system, the inquiries into the functions of the organs of special sense and the relations of these to the higher psychic functions, the experimental investiga-

tions bearing upon the functions of the cerebral cortex — all were utilized for the extension of clinical methods of examination, and for the interpretations of clinical findings.[3] Slow but sure progress was made also through the control of clinical studies by autopsies and the macroscopic and miscroscopic examinations of the brain and cord. Especial activity in such studies was shown by the clinico-pathological school at the Salpêtrière, of which Charcot was leader. English neurologists, notably Hughlings Jackson and Gowers, also made valuable contributions. These, with the clinical electrical studies of Duchenne, Remak and Erb, did much to increase the accuracy of diagnosis. The invention by Helmholtz of the ophthalmoscope permitted the direct observation of a part of the central nervous system (the papillæ of the optic nerves), a method of examination so important for differential diagnosis that every neurologist feels impelled to perfect himself in it. The study of the neuroses, especially after the introduction of the Weir Mitchell cure, helped to bridge the gap between neurology and psychiatry.

The laboratories of anatomy, physiology and pathology have afforded the data for the *diagnosis of the seat of lesions* and their nature. The localization has become more precise as these sciences have grown, passing from the gross terms cerebral, cerebellar, spinal and peripheral, through systemic, nuclear and segmental, to, more recently, the neuronal. Criteria for a *diagnosis of the nature of the lesion* have been drawn from pathological anatomy and physiology, and lastly progress has been making in the *diagnosis of the causes* of nervous diseases through advances in pathogenetic studies. Time will not permit even a sketch of the contributions to diagnosis made by the various laboratory subjects, but anatomy, physiology, pathology, anthropology, biology, chemistry, physics and pharmacology all have lent a hand. The nature of the infectious diseases which involve the nervous system — cerebrospinal meningitis, tuberculosis, syphilis, tetanus, influenza, leprosy, diphtheria — has been cleared up for us by bacteriological studies, and modern parasitology has revealed the mysteries of the coma of malaria and the sopor of African sleeping sickness. The clinical laboratories have applied the methods of chemistry, physics and biology and revealed to us the changes in the blood, the urine and the cerebrospinal fluid in nervous disease. New methods of examination are constantly being devised. Within a few months the workers in immunity problems have shown us how to demonstrate the presence of amboceptors for the syphilitic antigen in the cerebrospinal fluid of patients suffering from dementia paralytica. Each year we learn not only how to see, how to hear and how to feel more precisely, but actually to see, hear and feel things entirely new to us, to make observations of phenomena which all through preceding centuries have escaped detection by clinicians.

[3] *Cf.* Erb (W.): Ueber die neuere Entwicklung der Nervenpathologie und ihre Bedeutung für den medicinischen Unterricht. Leipzig, 1880.

In searching for disturbances of motility, sensation, reflexes, nutrition, speech, intelligence, emotion or will, the tendency of modern neurology and psychiatry is to become ever more objective, to exclude as far as possible the subjectivity of the examiner in observation and record, for in this way only is it possible to obtain results which are comparable and which can be utilized for science. Hospital records strive now in describing what can be seen, felt or heard, to use words of pure description unmixed with judgments or inferences, though that they still fall far short of their aim, every one who has occasion to consult these records knows. To counteract the errors of omission and commission of description, other still more exact methods of scientific registration are being more and more employed. Thus optic methods of reproduction, photography (simple, stereoscopic and cinematographic) are helpful in both neurology and psychiatry, and various graphic methods of investigating motor disturbances are gradually finding a place. The phonograph has been utilized for the registration of phonetic expressions, and the analysis of phonetic processes by motor graphic methods has been begun.

Perhaps the greatest progress making at present lies in the improvement of methods of investigating the psychic states and processes in nervous and mental diseases. The examination of the psychic side of a patient, often more important than the somatic inquiry, should, it is now realized, be carried out just as systematically and objectively as the examination of the physical condition. Psychiatry has suffered seriously from subjectivity. Thanks especially to the transfer of the methods of psychophysics to psychopathology, data are gradually being accumulated which are independent of the accidental subject of the observer. The principle of the " uniform stimulus " and the principle of the " reaction-time " have been adopted in the clinical psychopathic laboratory with gratifying results.[4] The testing of the perceptive faculty, the investigation of sense perceptions, the study of the orientation of the patient, the trial of memory, the examination of powers of work, and especially the inquiry into the characters of the associative processes, as conducted by the physician who has been well trained in the modern psychiatric clinic, permit of a precision and an extension to which the old clinical conversation could not attain. Though our knowledge of facts is as yet very incomplete, our comparable experiences with accurately studied material too small to permit of such reliable clinical formalizing in mental disorders, there can be no doubt that as we continue to observe what actually occurs in nature and to sift our observations empirically, separating as well as we can the essentials from the episodal in the disease-picture, we shall arrive at generalizations that will give us a diagnostic power in psychiatry equivalent to that we possess

[4] *Cf.* Kraepelin (E.): Der psychologische Versuch in der Psychiatrie. Psychol. Arb., Leipz., 1896, i, pp. 1-91. Sommer R.): Lehrbuch der psychopathologischen Untersuchungs-Methoden(Berlin u. Wien, 1899.

in other branches of internal medicine.[5] The certainty with which it is now possible to make the diagnosis and prognosis in dementia paralytica is an instance in point. Hallucinations, delusions and abnormal moods, it has deen discovered, are less essential for diagnosis than are disturbances of orientation and of the perceptive faculty, motor states and flight of ideas. Single disturbances not pathognomonic in themselves assume diagnostic importance according to their special grouping, as, for instance, in the well-known example of the different relations of confusion, excitation and orientation in kakatonia, mania and amentia. The widening of the functions of the anamnesis in history-taking by Janet and the emphasis laid upon the katamnesis by Kraepelin, have markedly enriched our diagnostic data in psychasthenic states in the one instance and in processes which terminate in dementia in the other.

Among the more interesting features of contemporary psychiatric diagnosis is the attention which is being paid to the so-called psychoanalytic method, as practised by Freud,[6] Riklin,[7] Jung.[8] Those who are working with Freud's method of investigating the psychology of daily life, of hysteria and of dreams are much impressed with the ingenious conceptions of that investigator and urge those who are skeptical not to condemn it on superficial examination or from prejudice due to Freud's over-emphasis of the rôle played by sexuality in the psyche. Some of the explanations which it is asserted the method affords almost remind one in brilliancy of the interpretation of the handwriting on Belshazzar's palace wall. The search for the hidden psychic complex, to which some painful emotion is attached, unbearable in conscienceness and accordingly suppressed, is proving to be a helpful idea in the study of psychiatric cases, Freud maintaining that the hallucinatory delirium may represent a compensation for unsatisfied desires, hinting that man sometimes resorts to a psychosis in order to find in its dreamy states that which is denied him in real life.

Further studies suggest that much light may be thrown upon paranoaic states by assuming that they, like the mental states of the hysterical, proceed from the suppression of painful memories, and that other symptoms in dementia precox — the weakness of apperception, the perseverations, the tendency to symbolism, the stereotypism, the command-automatisms, the apathy, the aboulia and the negativism (to speak in the slang of the psychiatrists) — may be determined more or less by the suppressed complex. Such an explanation, however, in order to account for the stability and resistance of the paranoid dement, contrasted with the mobility of the hysteric, has to assume a fixation of the affectivity in the one, possibly due to some metabolic intoxication (Jung), which is absent in the other.

A very great impetus would be given to neurological and psychiatric diagnosis in America if psychiatric clinics were to be established in connection with every great hospital or medical school. It is humiliating to think that this country, so far in advance in many other respects, is fifty years behind Germany, Italy and France in the recognition and satisfaction of this particular need. Since one in every three hundred inhabitants of this country is either insane or feebleminded, and the estimated cost to this country of psychiatric disease is, according to Dana, $85,000,000 annually, a cost which is increasing at the rate of 4%, the desirability of education in these matters is obvious enough. Half the money which was put into a temple recently reared by propagandists of a pseudo-scientific cult in Boston, in order to minister to certain psychic needs of some of the American people, would have been sufficient to build a first-class psychiatric clinic. The psychiatric clinics should come in America, and at once. Fifty years later is better than later! There can be no doubt that America will sooner or later lead in this, as she is doing in other sciences.

THE HISTORICAL DEVELOPMENT AND RELATIVE VALUE OF LABORATORY AND CLINICAL METHODS OF DIAGNOSIS.*

BY RICHARD C. CABOT, M.D., BOSTON.

PHYSICAL DIAGNOSIS.

I SINCERELY hope that this Congress and the year 1907 will mark an end of the false and harmful distinction expressed in the title of this address; the distinction, namely, between "laboratory" and "clinical" methods of diagnosis. My first reason for objecting to this distinction is that it is impossible of definition. No one doubts that we apply what are called *clinical* methods of diagnosis to the patients who consult us at our offices or in a hospital dispensary; yet in such cases nothing occurs "at the bedside," because the patient is not in bed. My second objection is that there are many methods which are carried out sometimes at the bedside and sometimes in the laboratory, the difference depending not upon anything inherent in the method employed, but wholly upon extraneous considerations. For example, an examination of fresh blood must be made at or near the bedside; while an examination of stained blood may be made either at the bedside or elsewhere.

It may be said that the distinction is a real one, though not coincident with the literal meaning of the words. It is often supposed that by *laboratory* methods of examination we mean the most *exact* instrumental methods, contrasting them with the *rougher* and more approximate processes used at the *bedside*. But this distinction is obvi-

*Read before the Congress of American Physicians and Surgeons in Washington, May, 1907.

ously fallacious, for we have few more exact instrumental methods than the measurement of temperature by means of the clinical thermometer; yet this is often carried out at the bedside, or rather in the bed (in case the patient is in bed) and not in the laboratory. The measurement of blood pressure, by Erlanger's apparatus, is a very delicate, difficult and exact method of examination, which (in bed-ridden patients) must be carried out at the bedside. It is exact, instrumental and clinical; yet it belongs to the type of methods which are often thought of when we speak of "laboratory" diagnosis.

But although the distinction cannot be defined and does not in fact exist, we *do* attempt sometimes (and most disastrously) to approximate to it. There are physicians who work wholly in the laboratory and others who never visit the laboratory. The distinction between the "laboratory diagnostician" and the "clinical diagnostician" is a real but a vicious one. There should be no diagnoses made merely in the laboratory, and none merely at the bedside, unless what are called "laboratory methods" are carried out, as they may be carried out, at the bedside. There should be no diagnoses made without regard to all the essential facts of each case; and there are few cases in which all the essential facts can be attained in the laboratory and few in which a "bedside" examination suffices.

All that tends to make us build up our diagnosis *at a distance from the patient*, and without the constant reminders of every side of his case given us by his actual presence before our eyes, — all such tendencies, I say, are dangerous. There should be no laboratory practitioners and no clinicians who do not understand and use "laboratory methods," so called. Instruments, accuracy and common sense are of importance in all types of diagnosis, and of no more importance in any single type than in any other.

The only true division between the kinds of investigation which should be carried out upon patients is the division between

(*a*) The work of experimental research, and

(*b*) The work of medical practice.

Experimental work, whether in the laboratory or at the bedside, needs a different kind of training, a different mental attitude, sometimes a different standard of accuracy, and above all a different distribution of one's time. Very few men can do both the work of experiment and the work of practical medicine; but every practising physician should do both what is called "clinical" and what is called "laboratory" work; that is, every man should work both at the bedside and in the laboratory, if he is to do the best for his patient.

THE IMPORTANT DISTINCTION BETWEEN EXACTNESS OF METHOD AND CLEARNESS OF STATEMENT IN DIAGNOSTIC WORK.

Does physical diagnosis tend towards greater and greater exactness of method? Is the greatest possible exactness desirable in all methods of physical diagnosis? I think not. Exactness, like an umbrella, is sometimes very much in place, and sometimes not. There are methods in use to-day quite uselessly exact, and others in which a greater exactness is very desirable. The degree of accuracy desirable in any diagnostic procedure is governed wholly by the ends to be secured. A pair of scales perfectly adequate for the weighing of hay would be far too rough and inaccurate for ascertaining the weight of a patient as it varies from week to week, while the scales used for this latter purpose would be valueless as a chemical balance. Yet, on the other hand, it would do us no good to have a pair of scales by which we could weigh our patients with a degree of accuracy equal to that of a chemical balance, for we could *do nothing with the results* when we got them. We could infer nothing from the slighter variations and time and money would be wasted in the attempt. When I see statements of blood counts which tell us, for example, that the patient had 5,633 leucocytes to the cubic millimeter, I cannot help making two comments. First, that the degree of accuracy to which the statement pretends is wholly useless; and second, that it is only the *pretense* of accuracy after all. It is pseudo-science and not science. Now, if there is one thing which we who try to do scientific work should avoid more than another, it is, I think, this *pseudo-scientific pretension*, — the appearance of accurary expressed in figures and diagrams, when there is no such accuracy in fact. All blood counts should end with at least two zeros, usually with three.

Another province of diagnostic work in which we have a great deal of the appearance without any of the reality of accurate work, is the quantitative estimation of urinary solids. Except in rare cases we can make no use of these figures; they do not tell what they seem to tell, namely, what the kidney is able to do, or what the metabolic processes of the body are accomplishing. The same is true of the quantitative estimations of acidity in gastric contents, as has recently been pointed out by Dr. Charles P. Emerson, in his most valuable work on clinical diagnosis. Our quantitative estimations of gastric acidity cannot possibly be more than roughly approximate, owing to the number of disturbing factors whose influence cannot be measured. Hence, it is a "fake" to express them in three decimals.

There are many other instances in which we have a great deal more of the appearance of accuracy than of the reality, and a great deal more accuracy than we can use even were it real. On the other hand, there are some of our diagnostic methods which are now very much rougher than we wish they were, and where a great degree of exactness is most desirable. For example, the intensity, duration and pitch of heart sounds and breath sounds are data at present, appreciable only in the roughest way, and our statements about cardiac and pulmonary diagnosis are consequently full of lamentably vague terms. Whether to call a given breath sound bronchovesicular or not, whether we say that a given heart sound is accentuated or not, must often be

very arbitrarily decided so long as we have no accurate methods of measuring these sounds.

What, then, is the immortal soul of this passing demand for general increase of accuracy in all places and at all times? It is, I believe, a demand for *clearness of statement*. Clearness of statement in regard to the results of our examinations is always and everywhere desirable; we cannot have too much of it. But this very clearness is often obscured by the use of figures and quantitative terms which mislead those who hear or read our statements. It is not only vagueness of statement, but the befogging of the sentence with statistics and figures that obscures our scientific writing. What we want to know from every man is — " Just what did you observe, and just what inference can be legitimately deduced therefrom? " About these matters we cannot be too exact.

TWO DOMINANT TENDENCIES IN PHYSICAL DIAGNOSIS.

(*a*) A tendency beginning to make itself felt in physical diagnosis is that which seeks *directness of contact* with the facts to be studied. Instead of conjectures about the condition of the bladder wall, conjectures based upon the subjective symptoms and upon the analysis of the urine, we are beginning to insist in all doubtful cases upon *direct inspection* of the bladder by means of the cystoscope. Methods of testing the amount of hemoglobin in the blood are more likely to be accurate if they can be carried out without processes involving dilution (and so errors), or contact with chemicals which may alter the coloring matter in some important respect. If we can compare the color of the blood directly with a standard, we have saved many chances for error. Dilutions and stains are of course necessary in many cases, but they all increase the likelihood of error in our results, and should never be used when more direct methods of examination are possible.

(*b*) Another tendency which I think will lead to very important results in the next decade shows itself in the distinction between *functional and anatomical diagnosis*, and in the increased importance attributed to the former. What we want to know is not only (or chiefly) whether or not lesions are present in any organ, but whether they interfere with the function of that organ or other organs, and if so, how far. Anatomical diagnosis asks: " How does the organ look and feel? " or " How would it look and feel if we could see it and feel it? " Functional diagnosis asks: " What can the organ do? How useful is it to the body? " Not appearance, but behavior, is more and more our interest. It is not of so much importance to know whether there is enlargement of the inguinal or axillary glands, or of the adenoid tissues of the throat, as whether these enlargements do any harm, interfere with any function. Especially is this distinction of importance in the field of gynecology. There are a dozen lesions in the adult female pelvis for every genuine interference with function; and the chief business of the diagnostician in this field is to discover which lesions to take seriously and which to disregard, which to treat and which to let alone.

" When you see a head, hit it: when you find a lesion, treat it." Such a maxim governs the practice of far too many physicians to-day. When we find a lesion, we should study with our best care, our best judgment and sense of proportion, all the facts in the case, with special reference to the question — " Shall I treat this lesion, or let it alone? "

THE VALUE OF SOME RECENT ADDITIONS TO THE TECHNIQUE OF PHYSICAL DIAGNOSIS.

The title of the subject assigned to me in this discussion bids me attempt an appraisal of the relative value of some of the different methods of physical diagnosis. To that attempt I now turn, choosing as best I can out of the many technical processes that might be passed in review.

First, the oldest and simplest methods are still the best; that is, yield the most information useful for the understanding and treatment of disease. Physicians looked at their patients and felt of them (that is, used " inspection and palpation ") long before they practised any other method of physical examination; but these methods still yield us a far larger bulk of useful information about our patients than any other methods. Percussion, although discovered earlier than auscultation, does not, however, as a rule, yield as much valuable information. When we come to the examination of the secretions and excretions of the body, the same statements still hold true. Here also inspection yields us the most important information. In nine out of ten cases, as I see them in private practice, I make no examination of the blood other than that afforded by direct inspection of the color of the blood when soaked into a slip of paper. The visual data about urine, sputa and feces are still the most important. I am excluding here, of course, the data obtained by microscopic examination, which, literally speaking, are part of inspection, but not part of that ancient and honorable type of inspection which historically precedes all other methods.

Passing now to some of the more recent methods of physical examination on which a judgment may be pronounced, I should say that:

(*a*) The diagnostic value of *fluoroscopy and radiography* is established beyond doubt for all diseases or suspected diseases of bone, and for all diseases in which the presence of concretions is suspected. In such diseases I think it is essential that the patient should have access to a competent practitioner of radiographic technic. On the other hand, I do not regard it as essential, or even of any considerable importance, that every patient suffering from diseases of the heart, lungs or stomach should be examined by the x-ray. Although it is true that x-ray examination occasionally yields us information of great value in diseases of these organs, yet such cases are relatively rare. I do not think that x-ray exami-

nation of these organs should become a part of the technic of every up-to-date practitioner.

(*b*) The estimation of *blood pressure*, and especially of systolic blood pressure, seems to me also to have proved its value as a part of the routine examination of every case in which disease of the heart, arteries, brain or kidneys is suspected. My reasons for this statement are as follows: We all of us believe that it is of value in diagnosis to estimate the tension of the radial pulse; but it has been abundantly shown by the testimony of many competent observers that even the experienced finger is not infrequently led into wide errors in judging pulse tension. Such errors can be detected only by the use of instruments for measuring blood pressure. It is true that the information obtained by the use of these instruments cannot always be directly utilized for therapeutic purposes, yet its value, although not comparable to that of methods of examination such as inspection, palpation or urinalysis, is considerable when we take account of the *speed* with which an estimation of systolic blood pressure can be made. The time-factor can never be left out of sight. Relatively time-consuming methods, such as the counting of red blood corpuscles, or the cystoscopic examination of the bladder, can only be utilized in a comparatively small number of cases where the information to be derived from them is of the greatest importance. On the other hand, blood pressure measurements can be so quickly made that we are justified in using them, and indeed bound to use them, in a large proportion of our cases, even though it is true that the information they afford is relatively slight.

(*c*) *Cryoscopy* is not, I believe, of any considerable value in the diagnosis of medical, as contrasted with surgical, disease of the kidneys. It is a time-consuming and difficult procedure, and its results need to be interpreted with so much skill and caution that they do not recompense us for the labor involved.

(*d*) *The use of simultaneous tracings taken from the heart* and from one or another of the *peripheral blood vessels*, in the way especially popularized and recommended by MacKenzie, affords a great deal of interesting information, but not, so far as I can see, anything of any considerable value to the practising physician.

(*e*) In the *examination of sputa* we have progressed from the complex to the simple. Reduced to its essentials, sputum diagnosis means to-day a good look at the sputa in bulk, the judicious use of one's nose and the search for tubercle bacilli "early and often." Curschmann's spirals, Charcot-Leyden crystals, fibrinous casts, influenza bacilli yield no important clues for diagnosis, prognosis or treatment.

(*f*) To immerse the patient in a *warm bath during palpation of the belly* is a procedure which recommends itself, I think, more and more to those who have given it a trial.

In difficult cases the warmth may produce so much relaxation as to make it needless to resort to an anesthetic.

SUMMARY AND CONCLUSIONS.

1. The attempted distinction between laboratory methods and clinical methods of diagnosis is a false and misleading one. The attempt should be abandoned once for all. But the distinction between *experimental* research (in the laboratory or at the bed-side) and *applied diagnosis* is important.

2. The degree of exactness desirable in any technical procedure is relative to the end to be secured. We may easily have too much as well as too little exactness. But of clearness in the expression of our results we cannot have too much.

3. Modern physical diagnosis shows (among others) two dominant tendencies: (*a*) To seek and prize the most direct methods of examination. (*b*) To lay stress on the present functional efficiency of an organ rather than on the presence or appearance of anatomical lesions.

4. The old methods — inspection and palpation — are still the best.

Among recent additions to our technical resources three may be mentioned as likely to stand the test of time. These are:

(*a*) X-ray examination.

(*b*) Blood-pressure measurements.

(*c*) Palpation of the abdomen beneath the surface of a warm bath.

Reports of Societies.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

TWENTY-FOURTH ANNUAL MEETING, HELD AT WASHINGTON, D. C., MAY 7, 8 AND 9, 1907.

THE meeting was called to order in the New Willard Hotel, by the President, DR. THOMAS DARLINGTON, of New York, May 7.

The President's address dealt with the source of pulmonary tuberculosis and its mode of infection. He believes that nostalgia is a great disadvantage in treatment at a distance from home. The good results at North Brother Island and at the Sea Breeze Hospital were noted. Typhoid fever and tuberculosis are much alike in the manner of implantation. The increase of heart disease was noted by charts and statistics were given from 1880 to 1905 for Boston, New York, Chicago, Philadelphia and ten other large cities in the United States. The most marked increase is shown in Boston, where the rate from heart disease was 11.71 in 1880 and 18.17 in 1905. New Orleans gives the greatest increase in the mortality due to Bright's, rising from 5.21 in 1881 to 17.30 in 1905.

Dr. Darlington believes that the vice of hard drinking is less prevalent than it was in the days gone by; drunkenness is less common, but stimulation is on the increase.

There is a growing tendency to promote the virtues of hygienic home treatment of tuberculosis at the expense of climatic treatment. The latter still has a most important place, but other methods are pushing to the front and must be considered.

The fresh air treatment of tuberculosis is not a formidable rival to the purely climatic cure. Without decrying my own city, it must be admitted that New York has a variable and most trying climate, yet we have a sanatorium for consumptives situated on North

Brother Island. This island stands at the junction of the East River and Long Island Sound, near that region very properly called Hell Gate. The climatic conditions at this point are distinctly unfavorable, and the patients received are mostly those afflicted with an advanced type of the disease. They are recruited from a class in whom good hygienic surroundings are at a discount; in fact, from the lowest strata of the "submerged tenth," yet the systematic routine of hospital existence, the outdoor life and good food give us results that are most encouraging. Apparently hopeless cases are being cured, and this is taking place despite climate, not with its aid.

The advantage of curing patients in the climate in which they must afterward live and the elimination of that most dreaded complication "nostalgia" are results of prime importance. No climate, however favorable, can avail much if homesickness develops, and the questions of the financial status of the patient and his future life are of too great significance to be overlooked. A contented mind is a therapeutic adjunct of the utmost value, as we all have had abundant opportunity to observe.

A study of the causative factors of this alarming increase naturally suggests the part played by the many so-called features of city life, and one of the most important factors in the relation of mental strain to the production of functional, followed by organic, lesions of the heart and subsequently the kidneys. The high-wrought, over-nervous activity of the modern city business man and the equally strenuous social whirl of the city woman; the mad rush of competition; the bustle, confusion, noise and unrest, so striking in comparison with the "*dolce far niente*" of the business and social life of a century ago; crowds and hurry; elevated stairs and "rapid fire" elevators; mental strain and physical bankruptcy — all seem so essential. They have come to be considered a striking characteristic of our national life; yet they are so deadly to our individual life that they furnish us with food for deep and earnest thought.

DR. SAMUEL A. FISK, formerly of Denver, now of Brimfield, Mass., presented a paper entitled

A SEARCH FOR A SUITABLE CLIMATE.

This account was largely personal and brought out the advantages and disadvantages of life in Colorado twenty-five years ago, before it became the Mecca for consumptives. Dr. Fish said that altitude *per se* is not a producer of hemorrhage of the lungs. He saw good results in cases of laryngeal tuberculosis, although the voice may be affected for years. Colorado climate must be used properly. It is not enough to simply get there, and then, metaphorically, draw a razor over one's throat by doing all sorts of imprudent things, which would not be entertained for a moment at home. But the climate rationally used is a great aid to the arrest and cure of most forms of phthisis.

DR. J. EDWARD STUBBERT: This seems to be in one sense an experience meeting; and, while I have never been in Colorado, I am extremely interested in Dr. Fisk's paper, from my own personal experience. I, also, was born in Massachusetts, near Boston. I also developed tuberculosis when seventeen. I was not sent to Colorado, was not sent across the Atlantic, but was sent to sea in the tropics. I came back with the disease, apparently, thoroughly arrested. Four years afterward I redeveloped it in New York City. The late Professor Loomis gave me three months to live. I spent short times in Lakewood, Atlantic City and in the Berkshires. I then went to China, where I stayed two years. There I lived in a climate where the sun shone five minutes in twenty-eight days. I came back from China and went South, where I stayed for a few months. I came back to New York City and then went to Central America, where I remained for five years. We all know what the climate of Central America is, showers from morning to night, with the sunshine in between. I then weighed 131 lbs. and now 186. Dr. Fisk and I, therefore, have two parallel cases, yet one went to Colorado and the other did not. One stayed at home and took short trips and the other took trips and went to Colorado. I have applied this rule to the treatment of many cases of tuberculosis, who had the means to travel and almost always with good results. Regarding a sea trip, I have crossed the North Atlantic many times, but would not send a patient there because of the necessity of being cooped up on the steamer. In almost every instance of what we call incipient tuberculosis, when I have sent patients to the South on a sea trip, they have recovered, for they could live and even sleep on deck. It seems to me that for our *patients* we should prescribe an out-of-door life and change rather than any specific climate.

DR. V. Y. BOWDITCH: In 1890, at the meeting of this Association in Denver, I said that if I were threatened with tuberculosis, I would make my way to Colorado as quickly as possible and I have had no reason to change that opinion since, unless it be, possibly, that with the lapse of years I prefered to die earlier at home. I desire now merely to put myself upon record to this effect. We now have advanced methods of home treatment for the vast number of patients who cannot go away. Every case should be judged upon its own merits. I still believe that under certain conditions the more radical change *is much* the wiser method.

DR. DELANCEY ROCHESTER, of Buffalo: I am interested in this matter of sending patients to different climates, and from my experience I have come to realize that there are two places to which we may with advantage send them, — Colorado and North Carolina. If I cannot send them to either of these two places, I do the next best thing in substituting the mountains around my home and in the Adirondacks. My last resort is to employ the home treatment in Buffalo. We ought not to try to substitute the home treatment of tuberculosis for the climatic treatment when we find such excellent results from the latter treatment.

DR. FISK: I do not want to take issue with Dr. Barlow, except to say that when we were in Southern California in 1902, one night at Redlands, I hung my clothes near an open window and they were so damp the next morning that I thought I would take cold.

DR. JUDSON DALAND read a paper on

ASSAM FEVER OR LEISHMAN — DONOVAN DISEASE.

This disease has until a few years ago been supposed to be confined to Assam and the Madras region, but recently it has been observed in Egypt and Arabia. The newness of the identification of this disease is such as to make it not impossible that we may find cases in our own states, or in the West Indies. There has been no case yet under my notice except those mentioned. The most important point of the paper is the fact that this organism is specific and peculiar to Kala azar and only found there. Last June the first successful observation was made regarding the feeding of the Kala azar to the bedbug, and the discovery of the entire cycle within the bedbug demonstrated the fact that the bedbug was the normal alternate host.

DR. JOHN W. BRANNAN, of New York, read a paper on

AIX-LES-BAINS.

The season is from May to October. From the latter part of August to the middle of September Dr. Brannan found it quite warm enough to discourage any exertion,

necessitating the advice to "laze and loaf." The waters have a temperature of 111° F. (44° C.) and contain carbonates and sulphates of lime, soda and magnesia, as well as barégine. The douche massage was described. The bathing room is equipped with two kinds of hose carrying water tempered to the desired degree. In one the water is under very high pressure and is used for douching the extremities; in the other it is under slight pressure and is applied to the back and the body. One doucher is placed in front and the other behind the patient, each provided with a flexible hose discharging great volumes of water in such a way that he can at will direct the water under high pressure, upon the different extremities, leaving both hands free for simultaneous massage of the muscles and joints. The other man gives attention to the back of the neck, shoulders and body. This process lasts eight to ten minutes and the water varies from 35° C. to 42° C. in different cases. The patient is carried back in a sedan chair to his room. Not much stress is laid upon a restricted diet by the physicians, except in gouty patients. Contra-indications are organic disease of the kidneys and liver and valvular disease of the heart with imperfect compensation. Comparison was made with Hot Springs, Virginia, whose waters are similar.

DR. F. CREIGHTON WELLMAN, of Benguella, West Africa, a corresponding member, sent a paper on the

CLIMATE, NATURAL HISTORY AND DISEASE INCIDENCE OF THE ANGOLA HIGHLANDS.

(Read by title.)

DR. PAUL M. CARRINGTON, surgeon in the Public Health and Marine-Hospital Service of the United States, presented a paper on the

CLIMATE OF NEW MEXICO.

This paper contains data on all the important stations in the territory and particularly of Fort Stanton, where Dr. Carrington has been stationed for over six years.

DR. FREMONT-SMITH, of Washington, D. C., read a paper on the

EFFECT OF FLORIDA CLIMATE UPON ACUTE AND CHRONIC DISEASE.

Having practised several winters at Palm Beach and St. Augustine, the author gave personal experience of the climate in its relation to disease. The frosts seem to be more severe of late than in previous years. The cold waves usually last about three days, followed by fair, sunny weather. The climate of St. Augustine or Ormond is not dry, nor is that of Florida in any part. It is moderately humid. St. Augustine stands upon a neck of land surrounded by the water of the sea, but separated from the open ocean by a narrow island forming the harbor. An account was given of the outbreak of typhoid fever at St. Augustine in 1902. Both Palm Beach and Miami are usually below the frost line. In 1899 the temperature fell once at Palm Beach to 33° F.; in 1906, to 25° F.; in 1907, to 28°. During each season there are at least three or four cold waves, sufficiently severe to render warm clothing and careful protection of the delicate imperative.

Dr. Smith then took up the incidence of dysentery, malaria and pneumonia and showed that they are rare. A good word was spoken for Nassau in the Bahama Islands.

DR. J. EDWARD STUBBERT read a paper on

SANITATION IN PANAMA,

and showed a series of lantern slides in illustration. Dr. Stebbert said that one cause of the great sickness that existed during the French régime was the filth and rank vegetation that covered the isthmus from one end of the line to the other. The situation of Colon was so low as not to permit of drainage. Street and house sanitation was carried out by Colonel Gorgas. Reservoirs were built; the Ancon Hospital was overhauled and mosquito bars supplied, subsidiary hospitals were established. Malaria runs a more rapid course than in the United States. Dr. Stubbert referred to a noted writer, who spent about eighteen or twenty hours on the isthmus, and then wrote a scathing article regarding its sanitary conditions. A picture was then shown of the reservoir supplying Colon, which this writer said did not exist, but which was there at the time of his visit. So greatly have the conditions been improved that in 1906 only 28 per 1,000 were on the sick list. The ratio of deaths per thousand was 41. There are now 87 physicians in the sanitary department, with 9 hospitals and one sanitarium.

DR. STUBBERT: In reference to the report of the death-rate on the Isthmus, I would like to say that I kept very careful records of the Nicaragua, Cuba and Panama death-rate. The official death-rate of Panama has never been tabulated. The death-rate on the Isthmus was enormous during the French *régime*. At Nicaragua it was .7 of 1%.

DR. J. M. ANDERS, of Philadelphia, read a paper entitled

A PRELIMINARY STUDY OF HEMOPTYSIS DUE TO TUBERCULOSIS.

Subdivisions were made into cases occasioned by either congestion of the bronchial mucosa and lung texture, or ulceration or erosion of vessels, or rupture of miliary aneurisms. He questioned whether, in point of intensity, the hyperemia of early pulmonary tuberculosis is equal to that of many other acute and chronic diseases of the lungs, in which the tendency to free bleeding is decidedly less marked. It is probable that minute areas of necrosis are responsible for these early hemorrhages. Chronic valvulitis affecting the mitral segments in cases of pulmonary tuberculosis is a cause of hyperemia and congestive bronchitis. Tables showing the relation of age, sex and seasonal influence were exhibited.

Dr. Anders believes that residence far removed from the seacoast is best for patients suffering from hemoptysis. Rarefied, dry air is best. Coughing must be controlled and hot and alcohol drinks forbidden. Aconite in one-drop dose every third hour is advised.

DR. E. O. OTIS, of Boston, read a paper on

THE BLOOD PRESSURE AS A GUIDE IN THE TREATMENT OF HEMOPTYSIS.

The severer hemorrhages were not considered, but rather the less severe cases occurring generally in the earlier stages of the disease and chiefly the recurrent or persistent forms. A Janeway sphygmomanometer with a wide cuff was employed, and the nurses at the Massachusetts State Hospital at Rutland were instructed in its use. The standard blood pressure for each case was established and was found to be 126 for men and 120 for women. In 18 recurrent cases, when the pressure was found high, the nitrites were given; when low, ergot was used. Ergot is too slow, however, to produce immediate results.

DR. DELANCEY ROCHESTER: From observations which we have been making upon blood pressure, I am convinced of the very slight effect of drugs of any sort in reducing blood pressure and of the very temporary effect of any of them. We have had cases of diseases of the kidney and of advanced arteriosclerosis, in which there was high blood pressure. In one case the blood pressure rose to 255 and then the instrument broke; how much higher it would have registered I do not know. No drug used in that case had any effect,

and in a number of other cases nothing but the nitroglycerin in solution made any impression upon the blood pressure. The effect of this was only for ten minutes, when there would be a fall of from 20 to 30 points and then it would rise again. The nitroglycerin in tablet had no effect. The amyl and various other nitrites were of no use at all. Sweating induced by hot air and steam baths and by hot foot baths, regulation of diet and use of purgatives were of some value.

DR. FISK: I desire to express my appreciation of Dr. Otis's paper and to suggest the beneficial effects of fresh air in coagulating the blood and of calomel in diminishing blood pressure.

DR. THOMAS A. CLAYTOR: I want to substantiate what Dr. Rochester has said about drugs having no effect in the reduction of blood pressure. Nitroglycerin and the nitrites have been of little value in my hands. Potassium iodide given over long periods has had rather more effect. Rest, diet and purgation have been about the only satisfactory methods in my hands of reducing blood pressure.

DR. FREMONT-SMITH: The value of the nitrites seems to lie principally in releasing the local spasm of blood vessels in which high tension exists. The nitrite of sodium and nitroglycerin in the neuralgias of various types dependent apparently upon local spasm of sclerosed blood vessels of are great value, as in certain headaches and in angina pectoris.

DR. R. H. BABCOCK: This paper is extremely interesting and suggestive. I was much struck with the fact that the average blood pressure in these cases was moderately high, — 126 mm., with the Janeway instrument. Most of us have had the impression that blood pressure in tuberculous patients is usually toward the lower reading. I agree that the nitrites and remedies of that sort do not materially lower blood pressue. I should suggest that, if in any case of hemoptysis the blood pressure were high, the measures to reduce it in addition to rest would be such measures as quiet heart action, because patients with hemoptysis are more or less excited or disturbed by reason of the symptom, and an excitement on the part of the heart raises the systolic blood pressure. Therefore, such measures as rest, morphine and gentle purgation would certainly be indicated in these cases. Where blood pressure is extremely low I should question the effect of ergot, believing that measures such as abdominal pressure or ligation of the extremities would really be more efficacious than the administration of ergot. I believe, indeed, that even digitalis would be of great benefit. Dr. Otis will see that I am still unconvinced as to the advantage of ergot in cases of pulmonary hemoptysis.

DR. THOMAS DARLINGTON: Not bearing directly upon the question of blood pressure, but upon the matter of nitroglycerin, I would like to say that within the last year the Department of Health made many analyses of tablets of nitroglycerin and in many instances the amount present in the tablets was so small as to be practically useless.

Another point in connection with nitroglycerin and of which I made some investigation over twenty years ago, is that in cases of poisoning by nitroglycerin it was found that ammonia immediately restores the color to nitrite poisoned blood; that is, ammonia with nitroglycerin is incompatible.

DR. OTIS: One of my objects in presenting these observations was to compare our experience with that of others, so as to obtain further light upon the relation of hemoptysis and blood pressure and thus, perhaps, arrive at something more definite and precise in treatment. Hemoptysis is not an uncommon occurrence; often persistent and recurrent, extending over weeks and months. I earnestly hope that others who see many cases in sanatoria or in private practice will observe the relation between blood pressure and hemorrhage and report their results. We may find that ergot still has its place in the treatment of hemoptysis.

DR. F. M. POTTENGER, of Los Angeles and Monrovia, Cal., read a paper on

THE RELATIVE VALUE OF HIGH AND LOW ALTITUDE IN THE TREATMENT OF TUBERCULOSIS.

Dr. Pottenger acknowledges that men are very much influenced by their surroundings and hence the difference of opinion on this question. After depicting the unfortunate condition of those who are sent to remote regions without proper means or safeguards, he made the proposition that a climate making great demands on metabolic processes requires a hardy man to endure it. Elevated climates fall in this class, are variable with seasons, and while the young and robust are particularly suited to such conditions, those in advancing years should be spared the excessive demand for tissue change. Rest is the better method of treatment of pulmonary tuberculosis.

DR. W. JARVIS BARLOW, of Los Angeles, reported on

TWO HUNDRED CHARITY CASES OF PULMONARY TUBERCULOSIS UNDER SANATORIUM TREATMENT AT LOS ANGELES.

Ninety-two per cent of the cases were beyond the first stage; they were mostly refined people reduced in circumstances. The paper showed very clearly that good results may be sometimes obtained by properly caring for those advanced in the disease. One is often astonished at what an improvement an advanced case, given up, makes when conditions have been made favorable. It is difficult to estimate the lives that may be saved by isolating these poor advanced cases, who are shut out from most of the charitable sanatoria. These 200 cases were treated during three and a half years. Raw eggs and olive oil are given to each patient. The oil is less expensive than cream.

Advanced cases are given a trial of three months and if the case showed progression, arrangements are made to send the patients to a place where family or friends can care for them. Many are sent back to the East. Advanced cases which make a marked improvement and begin to have normal temperatures are placed in cottages, so that, irrespective of the stage, there is no difference made in the cases doing well.

The problem of after-care was discussed and Dr. Barlow said that if financial conditions and housing capacity were larger, the ultimate results would seem to justify the indefinite care of undesirable cases.

Of the first 100 cases 93 showed on admission the second and third stages. Sixty-two per cent showed progression or died; 37% improved. Of the second 100 cases 91 were admitted in the second and third stages; 45% showed progression, or died; 55% improved.

DR. CHARLES DENISON, of Denver, exhibited a model of a "sleeping canopy," designed to afford tent advantages indoors and showed photographs of its adjustment.

Believing that deficient ventilation is responsible for most of our tuberculosis, great stress was laid on the susceptibility of the individual, and the need of fortifying the system and dispelling unreasonable fears. A camper in the Rocky Mountains can get so inured to the drafty air that he can sleep on the ground with the wind blowing 20 to 40 miles an hour and not think of "catching cold." So a sleeper, by having warm enough coverings on the bed and a thick woolen hood on the head in winter, or a light soft night-cap in milder

weather, can so temper the air movement that no danger of catching cold will result. The canopy is made of denim. Specifications and drawings were shown.

Dr. Richard Cole Newton, of Montclair, N. J., read a paper on

PERSONAL HYGIENE IN THE PREVENTION OF CONSUMPTION.

The lesson was drawn chiefly from the experience with our American Indians during the last thirty years. While they are not inherently more liable to infection with tuberculosis than is a white man under like circumstances, their exceedingly filthy habits and fondness for liquor and unventilated dwellings make the mortality from phthisis great. In the nomadic life they had new locations every little while, but in permanent quarters filth keeps accumulating. In the same region, where the white man suffers least from tuberculosis, the Indian sickens and dies. An analogy between the Indians and negroes was drawn. Experienced army officers say that the red man is gradually becoming weaker and more prone to sickness. Infection plays a secondary part in the production of consumption and so does heredity. The principal cause is a man's life habits.

Dr. Arthur K. Stone and Dr. Cleaveland Floyd, of Boston, read a paper on the

DAILY CARE OF CONSUMPTIVES AT A GENERAL HOSPITAL AS AN AID IN SOLVING LOCAL TUBERCULOSIS PROBLEMS.

Statement of the experiment of the House of the Good Samaritan in the care of ambulatory cases of tuberculosis; daily medical supervision; out-door treatment; good food; home supervision. Twenty-five patients thus cared for with small addition to the administration force of the hospital; cost per patient, very small; results, good. [To appear in this Journal.]

Dr. F. I. Knight, of Boston, read a paper on

THE IMPORTANCE OF SUPERVISION OF PATIENTS AFTER LEAVING SANATORIA APPARENTLY CURED OF TUBERCULOSIS.

[See a future issue of this Journal.]

Dr. Vincent Y. Bowditch, of Boston, and Dr. Walter A. Griffin, of Sharon, read a paper on

SUBSEQUENT HISTORIES OF ONE HUNDRED AND SIXTY "ARRESTED CASES" OF PULMONARY TUBERCULOSIS TREATED AT THE SHARON SANATORIUM.

[See a future issue of this Journal.]

DISCUSSION OF PAPERS OF DR. BARLOW, DR. POTTENGER, DR. DENISON, DR. NEWTON, DR. STONE AND DR. KNIGHT.

Dr. J. M. Anders: I was very glad to hear Dr. Barlow speak in favor of the treatment of advanced cases of pulmonary tuberculosis. I think there is too much inclination to abandon active measures in this class of cases, whilst, as a matter of fact, they are occasionally savable. In 1900 I read a paper before this Association, in which I took the position that the tuberculin test was absolutely reliable as a diagnostic measure. I am not surprised to hear Dr. Bowditch say that finding the tubercle bacillus is, perhaps, after all, the only reliable diagnostic test. In 1900 the consensus of opinion seemed to be in favor of the opinion before mentioned. Since that time, however, I have had occasion to change my mind a bit in regard to this question, because I find that while we get typical and unmistakable reactions, as a rule, in rare cases, we cannot eliminate intervening conditions; and the subsequent course of two of my cases proved them to be something else than tuberculosis. The tuberculin test is, however, an almost absolute sign of the existence of tuberculosis. The question of a close observation of cases after returning home from sanatoria is one of the greatest practical importance, especially to the general practitioner. I fear that the latter is too much inclined to either discharge these patients when they return from sanatoria apparently cured, or allow them to use their own judgment as to whether they need further treatment or not. No fact is better established and this was brought forward in the papers read here this morning, than that temporary arrest and even apparent cure is often followed by fresh exacerbations without obviously existing cause. It seems to be a part of the natural history or course of the disease. We fail in our plain duty when we fail to keep in touch with these patients after their return from sanatoria. In all cases in which I have been able to keep them under supervision, the necessity for such a course soon became apparent. As stated by Dr. Knight, when they return to their home environment resistance becomes lowered and they are especially susceptible to intercurrent attacks of bronchitis and influenza, and, more than this, if the latter is not properly handled, it will lead to a relapse of the original disease. The same fact is recognized with reference to cases of pleuro-effusion that are apparently cured; they often merge into pulmonary tuberculosis subsequently. These convalescents also require close supervision, being, for the most part, tuberculous subjects, and I think it is a reproach to the medical profession that so many cases of apparently healed pleuro-effusion are allowed to develop into pulmonary tuberculosis. If there were maintained a state of high physical health and efficiency this sequel would be, to a large extent, prevented.

Dr. Delancey Rochester: I desire to enter my protest against the position of Dr. Bowditch and Dr. Anders, that the tubercle bacilli are absolutely necessary for the diagnosis of tuberculosis, or that the presence of the bacilli is the only ultimate test of the presence of tuberculosis. I feel that we can diagnose tuberculosis of the lungs and be sure of it without the presence of the bacilli and without the tuberculin test. It is not necessary to go into details as to methods, but I am perfectly sure, however, that we can make an absolutely sure diagnosis without this method.

With reference to Dr. Stone's statement that their patients were supplied with cloth bags, in which were rubber bags supplied with paper napkins and that the bag could be disinfected after the napkins were destroyed, some one has suggested that the bags be of paper. They could be bought for a few cents and could be destroyed every day.

I think in the matter of nourishment between meals, Dr. Minor's point is very well taken. I instruct my patients in business to have milk delivered to them at the office, or to take it from home with two or three eggs mixed with it before leaving home.

Dr. E. O. Otis: The subsequent career of sanatorium patients who are discharged with their disease arrested is a very serious question and deserves careful consideration. With the increase of sanatoria throughout the country and consequent increase of discharged patients, the problem of what to do with them so that they may remain cured and be capable of remunerative work becomes insistent. The farm colony that has been proposed is one solution of the problem and offers many possibilities. It might naturally become an annex to the sanatorium and discharged patients could become hardened and "the cure" made more permanent, so that subsequently they could return to their occupations in the city under favorable conditions of work, or be placed in the country in different positions, where they could lead an outdoor life. The first farm colony of this kind to be inaugurated as far as I know in this country is at the Stony Wold Sanatorium, at

Lake Kushaqua, in the Adirondack Mountains, under the supervision of its founder, Mrs. James E. Newcomb, of New York.

DR. THOMAS W. HARVEY: I think that the literature which we have been receiving on tuberculosis, while it allows of the influence of the bacillus as a cause, gives much evidence of the prevalence in the minds of many medical men that the principal reason for the continuance of the disease is the presence of the general practitioner. He does not recognize the disease early enough, wants to keep it under his care, or sends it to the wrong place or sends it at the wrong time. The problem of the advice to be given concerning the immediate treatment of early cases of tuberculosis is almost as important as the question of their care after treatment in sanatoria. There are several elements in this question which I have seldom seen discussed. First, in choosing between treatment away from home and treatment at home, the question of sex is most important. Of the tuberculous patients whom I have had to advise in the early course of the disease, I have found that the women can be taken care of very often at home, but I have yet to see the man whom I have been able to take care of at home. That is due particularly, I think, to the fact that he is the money-earner. Even among the well-to-do the women can be taken care of better at home than can the men, in a percentage of ten to one. Second, the question of temperament. There are some men who will not submit to the discipline of sanatoria and have gone off by themselves and succeeded better. While the discipline received at sanatoria is most valuable to themselves, to their families and to the community, there are individuals upon whom it seems to have an antagonistic effect.

DR. LEONARD WEBER, New York City: I believe if there is any disease common to man, the development of which depends on social conditions, it is tuberculosis, particularly tuberculosis of the lungs. It is true that by sanatorium treatment, public and private, by home treatment and by hygienic measures, much has been accomplished, but few cases of permanent cure of pulmonary tuberculosis occur and we shall stay far from curing until we find a specific remedy. We are accustomed to look at the tuberculous man only, tell him what he should and should not do, and to the working man how to live in order not to get tuberculosis; but I think this society must also look at the other man who is responsible to a very large extent. I mean by that, those men who run factories over time, who employ child labor, organize and run sweat shops; who build miserable tenement houses, get high rents and give little air and sunshine for it, together with all the other unhealthful conditions which lay the foundation for tubercular disease, not only in the feeble but in the rugged. The employer of labor, the builder of tenements and the owner of houses in unsanitary conditions ought to be looked after; they often need admonition and instruction and restraint to prevent infection and spread of tubercular disease.

DR. BOWDITCH: I am very glad that Dr. Rochester brought up the question of diagnosis without the presence of tubercle bacilli in the sputum. It only shows that when one has a distinct impression in his own mind, he often fails to impart it to others. I would be willing to stake whatever reputation I may have had upon the truth of my diagnosis, simply from the history and from the physical signs alone. What I intended to say in my paper was that the tuberculin test had been given in certain cases in which bacilli were not found simply as an additional proof of a previous diagnosis, in order to convince the "doubting Thomases" that tubercular disease was present. At the same time I meant to state that the final convincing proof of the presence of tuberculosis is shown in the appearance of bacilli in the sputum.

DR. PHILIP MARVEL, of Atlantic City, reported

TWO CASES OF PAROXYSMAL TACHYCARDIA, WITH BRIEF REFERENCES TO OTHER CASES ALREADY REPORTED.

CASE I was that of a woman aged forty-eight, who had seizures in which faintness and oppression in the chest were prominent symptoms. These recurred every month or six weeks. Dr. Marvel saw her in an attack of indigestion with severe cramplike pains in the abdomen, a dysenteric diarrhea, with considerable tenesmus and nausea, following a hearty meal, including crabs and oysters; after which she remained in the surf almost continuously for two hours. Her temperature was subnormal and she was pallid, with colorless lips. Dr. Marvel used external heat, enteroclysis, morphia hypodermically with digitalis later. The pulse had then risen to 192 by the following day. On the third day she had recovered.

CASE II was that of a physician aged fifty-five, who was convalescent from grippe. Two weeks after arrival at Atlantic City, he was seized with a night attack of "over-action of the heart," as he expressed it. The pulse was about 200, feeble and accompanied by a sense of oppression and fullness about the cardiac region. These attacks had occurred during three years and occasioned great apprehension and extreme anxiety. A hypodermic of morphia allayed his fear, although the rate of the heart continued rapid. In a fortnight he had another attack and after three more weeks another very severe one, the pulse rising to 210. He had an attack of nephritic colic two weeks later and seven months after an operation for calculus of the kidney; he died of pneumonia.

DR. JAY PERKINS, Providence, read a paper on

CARCINOMA OF THE MEDIASTINUM SIMULATING ANEURISM.

A miner, thirty-three years of age, who for several years had worked hard in the Klondike, suddenly developed marked enlargement of the neck, followed by dilatation of the superficial veins of the whole body, accompanied by double murmur at aorta and later great enlargement of area of cardiac dullness, including dullness over whole of sternum, lower right chest (and before death whole right chest), and some enlargement of glands above right clavicle and in right axilla, x-rays showing pulsating mass to left of spine at arch of aorta.

Autopsy: Small carcinomatous growth pressing on superior vena cava; large carcinomatous growth under upper part of sternum; tuberculous infiltration of right lung. Heart and aorta normal.

DR. THOMAS A. CLAYTOR, Washington, D. C., read a paper on

DILATATION OF THE HEART.

After considering the many cases of cardiac dilatation in which we can find a definite and tangible cause, there still remains a fairly large class in which we are not able to find any perfectly satisfactory explanation. We must fall back on the nervous system and say that the cause is loss of muscular tone.

Dr. Claytor cited a case of a lawyer who, though well advanced in years, had always been a man of remarkable vigor, who brought on the symptoms of a dilatation by the preparation of a long and important brief. He had just concluded his arduous task when he was suddenly seized with dyspnea and oppression in the cardiac region. Dr. Claytor found the heart considerably enlarged, acting very irregularly and a

mitral systolic murmur present, but it was not determined whether this was due to a true valvular lesion or to a relative insufficiency from dilatation, as the patient fortunately recovered.

In another case, that of a woman aged forty, who for a long time had the physical signs of a mitral stenosis and then developed a broncho pneumonia, with a very harassing cough. After a few days of constant coughing, marked orthopnea with edema of the lungs developed. Examination showed a loud systolic murmur in the tricuspid area, in addition to the pre-existing mitral stenotic bruit; caffeine in liberal doses gave fairly prompt relief and the wall of the right ventricle so far regained its tone that the systolic murmur was soon scarcely audible.

DR. CHARLES E. QUIMBY read a paper on

SOME MANIFESTATIONS OF ARTERIAL TENSION.

Dr. Quimby said that arterial tension, excluding syphilis and alcohol, is always a functional, not organic, condition, at first; a result and symptom, not a primary or direct cause. It is a symptom common to, and the only common symptoms of, many diverse and apparently unrelated (so-called) diseases. As such it points to their dependence upon a common cause, however diverse the symptom-complex; and thereby leads to recognition of the fundamental cause, with appropriate treatment. Illustrative cases.

DR. HOWARD S. ANDERS, Philadelphia, presented a paper on

INFLUENZA AND WEATHER INSTABILITY.

Medical history is generally meager in meteorologic studies as related to most diseases, even in those which give *prima facie* evidence of being affected by meteorologic states. Tuberculosis is a partial exception. Epidemic influenza also. Writer's initial and serial studies since 1899. Recent recurrence of influenza in winter of 1906-7. Conclusions from former studies. Data and inferences from latest phenomena. Day-by-day weather instability and frequency and extremity of changes probably more to blame for susceptibility to influenza and its virulence than is shown by any study of monthly averages of barometric, thermometric, hygrometric, or sunshine percentage readings.

At the business meeting a memorial of the late Dr. S. E. Solly, of Colorado Springs, was read by DR. JAMES A. HART; a memorial of the late Gen. Charles H. Alden, U. S. A., by DR. ROLAND G. CURTIN; a memorial of the late Dr. W. C. Glasgow, of St. Louis, by DR. GUY HINSDALE.

The following officers were elected for 1908: President, Dr. Thomas D. Coleman, Augusta; Vice-Presidents, Dr. Judson Daland, Philadelphia, and Dr. Charles Fox Gardiner, Colorado Springs; Secretary and Treasurer, Dr. Guy Hinsdale, Virginia Hot Springs; Member of Council, Dr. Thomas Darlington, New York.

Next place of meeting, Boston, June, 1908.

Book Reviews.

Treatment of Skin Cancers. By W. S. GOTTHEIL, M.D. Third edition. Revised and enlarged. International Journal of Surgery Company. New York.

In this third edition of Gottheil's little book, the chapters on treatment have been entirely rewritten and more than doubled in amount. Special attention has been paid to the subjects of the x-ray, radium and the high tension current in the treatment of skin cancers. The claims of arsenic as a therapeutic agent are still highly extolled.

Indigestion. By GEORGE HERSCHELL, M.D., London. Third edition. 282 pages. Entirely rewritten. Chicago: W. T. Keener & Co.

A text-book devoted to the diagnosis and treatment of the functional derangements of the stomach. A new section has been introduced in this edition which takes up the selection and preparation of food for dypsepties.

Essentials of Diseases of the Skin. By HENRY W. STELWAGON, M.D., Ph.D. Fourth edition, thoroughly revised. Philadelphia: W. B. Saunders Company.

In this fourth edition of Stelwagon's "Question Compend," the entire book has been subjected to a careful scrutiny and revision. Several of the more rare affections, such as blastomycetic dermatitis and hydroa vacciniforme, have been described.

Manual of Operative Surgery. By JOHN FAIRBAIRN BINNIE, A.M., C.M. (Aberdeen), Professor of Surgery, Kansas State University, Fellow of the American Surgical Association, etc. Third edition, revised and enlarged; with 678 illustrations. Philadelphia: P. Blakiston's Son & Co. 1907.

Binnie makes an apology for this third edition, but no apology is needed. Since the first edition was issued some four years ago, we have regarded this book as the best manual of operative surgery published in the English language. In his writing of scientific English Binnie displays two admirable traits, — he quotes profusely and comprehendingly from other writers, and he punctuates their conclusions with searching practical suggestions of his own. He is a tireless reader, who searches the literature. He is a helpful and stimulating writer who presents facts in such a fashion that he who runs may read. Again, without hesitation, cheerfully and confidently we commend this book to operating surgeons.

Post-Operative Treatment. By NATHAN CLARK MORSE, A.B., M.D., of Eldora, Iowa. Second edition, revised and enlarged. Containing 5 plates and 175 other illustrations. Philadelphia: P. Blakiston's Son & Co. 1907.

This second edition of Morse's useful book, following close upon the first, suggests the popularity of the writing and the need of such a work. The new edition is some thirty pages longer than the first, but essentially it is a reproduction of the book as published two years ago.

For the general practitioner and busy surgical assistant this book must be of service. Morse does not pretend to give us an elaborate original essay on post-operative treatment. His pages are filled with carefully selected extracts from the writings of others, and occasionally his own preferences are expressed.

The publishers have done their work well. The letter press and illustrations are good.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 1, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

BOSTON CONSUMPTIVES' HOSPITAL.

ALTHOUGH not widely advertised, the work of the Boston Consumptives' Hospital Trustees has been extremely active since their appointment as a board. As is generally known, land has been secured in Mattapan for the proposed tuberculosis hospital and measures are being taken to construct buildings as speedily as possible for the reception of patients. In the meantime, however, the board has turned its attention to matters of equal if not greater importance in its efforts to combat the disease by methods which accumulating experience has approved.

A step of great significance is the establishment of a dispensary or out-patient department in the city proper, which it is expected will be open for the reception of ambulatory patients early in September, if not before that date. For this purpose the property at 13 Burroughs Place has been secured, and is being equipped with all that is necessary for the complete examination of patients who may present themselves. In connection with this dispensary there will be a laboratory in which bacteriological work, and such other as relates to the problem of tuberculosis may be efficiently carried on. Dr. W. T. Councilman has been appointed pathologist to the dispensary, and the staff of physicians, under the headship of Dr. E. A. Locke, is ready to undertake the work which the proper conduct of the dispensary will entail. The hospital, which is as yet unconstructed, and this out-patient department are both to be under the superintendence of Dr. Simon F. Cox, whose admirable service in connection with the Long Island Hospital will be remembered.

It is the intention of the trustees to open this dispensary at first several mornings a week, and later, as the demand comes, to make it available also afternoons and evenings. The essential idea is to get as near the real tuberculosis problem in this city as is possible. To this end homes will be visited by a nurse who will be capable of examining into the conditions and instructing families in such measures against the disease as may be necessary. Milk, eggs and proper food in general are to be supplied to the sick, and, when necessary, to those of the family who may still be free from the disease. When the home is found not to be hygienic, assistance will be given in finding a more suitable place of residence. It is furthermore expected that families will be examined for tuberculosis or other diseases and referred to the proper country homes or hospitals, as the situation may demand. Cases are to be tabulated by families, by houses and mapped out by streets. Perhaps more important than all the other measures which we have suggested will be the attempt to eradicate the sources of contagion, which it is now generally acknowledged are the late cases which have hitherto found scanty consideration in our combat against the disease. The class work instituted by Dr. J. H. Pratt in this city will be further developed and taken up on a considerably larger scale than has hitherto been possible.

From the foregoing it appears that the trustees have conceived the admirable idea of constituting this out-patient department in the city proper a clearing house, as it were, for all cases of tuberculosis at whatever stage of the disease they may be. The design of the hospital at Mattapan is to care for the chronic and in great measure hopeless cases throughout the city; but this most important work does not in the least preclude the effort toward proper classification, which is eminently desirable in the present state of the problem. If it could be generally understood that this out-patient department in Boston is the tuberculosis center, where all cases may present themselves for examination and as a preliminary to their proper disposition thereafter, it is evident that a policy of centralization would be organized which would be of the greatest possible significance and value. At present, for example, applicants for the State Sanatorium at Rutland are examined at the Massachusetts General Hospital and other places in the city. The new plan, if carried out, would obviate this necessity, since all such patients could be examined at the new out-patient department at great economy of time and the avoidance of possible confusion. The management, also, of the special Boston

hospital, although itself caring for a very small proportion of the patients seen, would come to have an increasingly accurate knowledge and control of the entire tuberculosis situation throughout the city, which would naturally be a source of increased efficiency.

It is not to be questioned that the Board of Consumptives' Hospital Trustees has inaugurated a wise and feasible plan and placed its execution in most competent medical hands. It will naturally take both time and accumulated experience before so comprehensive a scheme can reach the stage of complete efficiency, but with the co-operation of hospitals, special societies and individuals it is not to be doubted that the centralization which is evidently desirable will in time be accomplished. We cordially commend the plan as we understand it in all its bearings.

LABORATORIES IN THE MEDICAL CLINIC.

The growing complexity of clinical medicine is well shown by the progressive development of the laboratories of a modern clinic of medicine. A comparatively few years ago the equipment of a clinical laboratory consisted of hardly more than a few test tubes, a half dozen bottles of reagents and a microscope, and these were amply sufficient for the demands coming from the bedside. The advent of bacteriology and its attendant methods of serum diagnosis brought a more extensive laboratory techinque into routine usage. Since those days the laboratory as an adjunct of the medical clinic has extended its scope much, so that now the modern clinic, to be well equipped for the routine study of cases and for clinical investigation, must possess a complex laboratory plant, where may be applied the methods of physiology, chemistry, bacteriology, pathology, physics and biology.

The attempt to meet these demands in this country has been made for the most part through the pathological laboratory with subsidiary departments of bacteriology, clinical pathology or chemistry in individual cases. By this means much valuable work has been done, but in most cases there has been an appreciable gap between the clinic and the laboratory, due to the fact that the pathologist at present in charge of most of these laboratories is not a clinician and so not accustomed to see the clinical aspect of possible problems. Thus the problems arising from the clinic are apt to be overlooked, or not fully appreciated. This may be said without belittling the work of the pathologist, for he has a definite place in the hospital equipment, with many fields of activity, which he has or is still working productively.

There is, however, gradually growing in America the idea of the laboratory of clinical medicine, directed by a head primarily a clinician, dominated by the problems of the clinic, peopled by those in training for clinical work and having the aid of men specially trained in chemistry, biology and physics. A recent number of the *Johns Hopkins Hospital Bulletin* (June–July, 1907) has a description of the laboratory organization of that hospital, which is of interest in this connection, with its subdivisions into a general clinical laboratory, a biological laboratory, a physiological laboratory and a biochemical laboratory, each with its own head. The chief features of this laboratory group are their compact organization, close association with the wards and the possibility of the solution of a wide range of clinical problems. The eighteen contributions from these laboratories which follow the introductory description of the organization and equipment show well the desirability of such a plant, though in type the inspiring enthusiasm of such a group of workers is inadequately shown; that can only be appreciated in a visit to a clinic of medicine so organized. In Germany such laboratories for some time have been adjuncts of the better medical clinics and explain in good part their activity in medical investigation. It is gratifying to see a similar development begin in America.

CONFERENCE ON SLEEPING SICKNESS.

An international conference on sleeping sickness has recently been held in London. Although this disease is peculiar to Africa, there is evidence that through the increase of communication between tropical and semi-tropical countries a spread of the disease is likely. This has, in fact, already occurred to a considerable and somewhat alarming extent. It has appeared on the Egyptian Soudan on the north, has entered Rhodesia and is threatening Zululand. White men are not immune, and it is not as yet understood exactly what climatic conditions are essential for the life and propagation of the fly which is apparently the temporary host of the germ of the disease. It is known that the fly haunts regions rich in water and foliage such as are found in tropical countries, and it is a matter of apprehension lest the flies be carried into those regions where white settlements are situated. If this should occur, it is feared that the progress of the

disease would be extremely rapid owing to the lack of immunity of the white races. The fatality of the disease is hardly appreciated by those who have not been brought into intimate contact with it. In epidemic form it is said to be more destructive than any other disease known. In Uganda, for example, which is the most infected area, it is stated that, out of a total population of 300,000, 200,000 have died. In view of these facts, it is apparent that the investigation of the disease, already well advanced, should be prosecuted with the greatest possible vigor. It is established that an animal parasite is the cause of the disease, which has been named Trypanosoma Gambiense, and that this parasite is presumably injected by the bite of a certain fly. Whether or not this fly is the sole bearer of the parasite and many other matters of detail are not as yet definitely determined. With our present knowledge of parasitic disease, however, and the extraordinary impetus which this line of investigation has recently been given, there is small reason to doubt that this increasingly fatal disease will before long be understood and mastered. It is a matter of the greatest possible importance to the colonization of Africa.

MEDICAL NOTES.

AN ARMY HOSPITAL. — Plans have been completed for the establishment of an army general hospital and medical station in the District of Columbia. A hospital building is now under construction, and it is intended to remove to this site, which is beyond the present Soldiers' Home, the army medical school, now on the Smithsonian Reservation. It is expected that a post-graduate school will be established for newly appointed assistant surgeons and for older officers who may wish to take up some special line of study. When completed, the hospital will be the largest of its kind under government supervision and will number many buildings. The site overlooks the national capitol, and the hospital is to serve as a memorial of the late Major Walter Reed, in recognition of his distinguished services in the investigation of yellow fever.

MEDICAL LEGISLATION IN THE NAVY. — It is hoped by naval medical officers that legislation favorable to the hospital corps of the navy may be accomplished at the coming session of Congress. An increase of pay and reorganization of the service is regarded as essential if suitable men are to be secured in the future. A recommendation in favor of the establishment of a dental corps will also be presented and an effort made to permit the employment of women nurses, particularly at naval hospitals.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 31, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 51, scarlatina 21, typhoid fever 11, measles 38, tuberculosis 33, smallpox 0, leprosy 0.

The death-rate of the reported deaths for the week ending July 31, 1907, was 16.94.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, July 27, 1907, was 173, against 211 the corresponding week of last year, showing a decrease of 38 deaths and making the death-rate for the week 14.80. Of this number 96 were males and 77 were females; 168 were white and 5 colored; 110 were born in the United States, 56 in foreign countries and 7 unknown; 32 were of American parentage, 115 of foreign parentage and 26 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 48 cases and 2 deaths; scarlatina, 18 cases and 1 death; typhoid fever, 20 cases and 1 death; measles, 58 cases and 4 deaths; tuberculosis, 48 cases and 18 deaths; smallpox, 0 case and 0 death. The deaths from pneumonia were 11, whooping cough 0, heart disease 19, bronchitis 4 and marasmus 5. There were 10 deaths from violent causes. The number of children who died under one year was 38; the number under five years, 57. The number of persons who died over sixty years of age was 26. The deaths in public institutions were 63.

There were 4 cases and 3 deaths reported from cerebrospinal meningitis during the week.

APPOINTMENT OF DR. MOOERS. — Dr. Emma W. Mooers, formerly assistant pathologist at the McLean Hospital, Waverley, Mass., has recently accepted a position in the University of Munich where she is now assistant instructor in the Psychiatrische Klinik of which Kraepelin is the head.

BEQUEST TO MASSACHUSETTS CHARITABLE EYE AND EAR INFIRMARY. — By the will of the late F. R. Sears, of Nahant, Mass., $20,000 is left to the Massachusetts Charitable Eye and Ear Infirmary, the income to be used to promote the happiness of the patients of the institution. Mr. Sears never had an official connection with the institution, but was particularly interested in its work.

Gift to Lynn Hospital. — Mr. Charles H. Newhall, of Lynn, has given to the Lynn, Mass., Hospital corporation 10,000 square feet of land adjoining the present hospital grounds. Mr. Newhall is vice-president of the hospital corporation and one of the chief benefactors of the institution. By the acquisition of this land the property will be protected and opportunity offered for future expansion.

Meeting of Massachusetts Association of Boards of Health. — At the quarterly meeting of the Massachusetts Association of Boards of Health, held last week on Gallup's Island, Boston Harbor, papers were read on Recent Public Health Legislation, by Dr. Henry P. Walcott, chairman of the Massachusetts State Board of Health, and Frank K. Wheatley, Senator from Plymouth County.

NEW YORK.

Bequests to Hospitals. — By the will of the late Mrs. Susan A. R. Moses, of Brooklyn, N. Y., the sum of $50,000 is left to various religious and charitable institutions. Among the charitable bequests, some twenty in number, are $5,000 each to the Brooklyn Home for Consumptives and to the Cottage Hospital of Laconia, N. H.

Wainwright Westchester Sewer Bill. — Governor Hughes has signed the Wainwright Westchester Sewer bill. This provides for the construction of a great sewer through a considerable portion of Westchester County, which is to empty the sewage of the district, including the large towns of White Plains, Mount Vernon and Yonkers, into the Hudson River. Much opposition was at one time brought to bear against the passage of the bill, particularly by the Merchants' Association of New York, on the ground that the sewer, with its outlet just below the city of Yonkers, would tend to increase the pollution of the Hudson's waters; but it is stated that this opposition was afterwards withdrawn when the bill had been amended in such a way as to obviate the menace to public health which was involved in the original measure.

3. Arneill calls attention to the frequency of enteroptosis with functional gastric and intestinal symptoms in pulmonary tuberculosis. These often cause the patient to limit his diet to the point of starvation. The patient's symptoms which result directly from the tuberculosis may be completely overshadowed by the psychoneurotic dyspeptic complaints. It is of great importance, therefore, that these receive proper treatment, largely by suggestion, rest, generous feeding and general correction of mode of life. A thorough investigation of digestive functions is often desirable, but in most cases the indigestions which arise in the course of pulmonary tuberculosis, too often as a result of over-feeding, can be treated along symptomatic lines, by bitter tonics and hydrochloric acid or by alkalies and antifermentatives. In general, incipient cases do not show abnormality of gastric analysis. Cases of moderate advancement show most often hypochlorhydria, but occasionally hyperchlorhydria; and advanced cases show diminished or absent hydrochloric acid and pepsin with diminished motor power. When this loss of motor power is due to enteroptosis, relief may often be given by means of adhesive plaster bandages or abdominal belts. The danger of over-feeding must not be disregarded; forced feeding should be persisted in only until nutrition has reached an eminently satisfactory point; it should not be pushed to the point of producing indigestion and obesity.

4. Connor has collected observations from 51 authors of 147 cases in which the opacity of incipient cataract has wholly or in part disappeared and the lens has regained its transparency. The occurrence of this phenomenon is admitted to be rare.

8. Munson reports a case of collapse and death in which at autopsy there was found to be hemorrhage in both suprarenal glands. Suprarenal hemorrhage is said to be very common in still-born and very young infants, but in adults it is comparatively rare. Clinically the cases simulate peritonitis or internal hemorrhage, show symptoms of suprarenal insufficiency (*i. e.*, prostration, loss of weight, diarrhea) or resemble apoplexy.

11. Elliott finds, contrary to the assertions of Potain and Teissier, that the blood pressure in uncomplicated diabetes is not increased. In severe progressive forms of diabetes, in young spare individuals, there was distinct hypotension.

12. Solis-Cohen reports 27 personal cases of latent diphtheria, in which no membrane was visible. In most cases there were slight symptoms in the throat. He further cites the findings of other investigators who obtained positive cultures in considerable percentages (3% to 29%) of large numbers of children with sore throats. He maintains that the prevalence of diphtheria is due to these latent cases, and to the so-called "carrier" cases in persons who have been in contact with patients with diphtheria and harbor the bacilli without showing symptoms. He urges that all cases of sore throat should be examined bacteriologically, that latent cases and infected "carriers" should be carefully sought out and isolated.

13. Searcy describes the occurrence of an epidemic in a colored insane hospital in Alabama which he finally identified as pellagra. The disease has never before been reported in the United States, but in all likelihood has occurred unrecognized. It is met in nearly all European countries, especially those bordering on the Mediterranean, and is due to the continuous eating of damaged corn. Poor hygienic surroundings and exposure to sun are thought to have a predisposing influence. The first symptoms are a

general lassitude and weakness, soon followed by gastric and intestinal disturbances, sore mouth and skin lesions of vesicles and bullæ most commonly on the backs of the hands and wrists. Patients take to bed on account of weakness; they are dull and depressed but complain little of any pain or discomfort. The temperature rarely rises more than a degree and a half above normal. Fatal cases die from one to several weeks after taking to bed from progressively increasing weakness. Where recovery occurs it occupies months. In diagnosis scurvy, acrodynia, purpura and erythema multiformæ are to be excluded. Post-mortem findings include pachymeningitis, some sclerosis of the brain and cord and fatty degeneration of internal organs. In the author's 88 cases there were 57 deaths. Of the whole number only 8 were males. Eighty per cent had been in fair or good health previously. No nurses had the disease. The corn meal used at the hospital proved on examination to have been made of mouldy grain and to contain quantities of bacteria and fungi. After this was changed no new cases developed.

5. LEAKE, H. K. *Chronic Perforating Ulcer of the Bladder.*
6. DORAN, W. T. *Report of a Postoperative Case of Fibroid Sarcoma Under the Enzyme Treatment.*

3. Bissell makes a plea for accurate diagnosis, thorough examination and ample deliberation in cases of tumors of the breast, since gummata of the breast are not extremely rare, and they can be cured by mercurial treatment without mutilation. After reviewing the differential diagnosis of tumors of the breast, and giving the history of five cases of syphilitic tumors of the breast observed by him, he gives the following conclusions: That as a rule late syphilitic lesions of the breast can be quite easily differentiated by careful diagnosis, and certain breasts can be saved from operation. In case of doubt we should resort to the rapid administration of mercury by hypodermic injection, and see what effect it has on the tumor.

2. Recognizing the common observation of a relative dullness with prolonged and high-pitched expiration and increased voice sounds at the right apex which may be physiological, Billings has devised a method of examination which in his belief will serve to identify the pathological cases. He asserts that in cases of "physiological intensification" the increased intensity of the breath sounds is present over the lower portion of the right upper lobe as well as at the extreme apex; whereas in early tuberculosis the intensity at the apex is out of proportion to that over the lower portion of the upper lobe. To obtain numerical values representing the intensity of breath sounds at different points he uses a modification of the Oertel stethoscope. By means of this in 100 normal chests, 22 of which showed physiological intensification at the right apex, he found that the ratio of intensity of breath sounds at the apex to that of the sounds over lower portions of the right upper lobe was 5: 4 or 5: 3. In 22 cases with tuberculous infiltration the ratio was 2:1 or greater. He believes that a ratio of 5: 2 or less establishes a probability of pathological infiltration.

6. Coakley in observing the pupils of a rabid dog noticed extreme contraction of the pupils which resisted mydriatics, but within an hour of death gave place to sudden dilatation. The contraction of the pupils was greater than could be produced by morphine or other drugs, the effect of which was tested. In 114 dogs with rabies examined the contracted pupil was present in a great majority. Coakley believes that this condition of the pupils resisting mydriatics followed by dilatation a few hours before death is pathognomonic of rabies.

8. MACNAUGHTON-JONES, H. *Important Epochs in the History of the Old School of Medicine in Paris.*

3. Cheyne gives the details of two cases of intermittent hydronephrosis with operation. This consisted in a nearly complete transplantation of the ureter from the upper part of the pelvic sac to the lower part of the sac thus allowing free escape of urine. The results in his two cases were very satisfactory.

4. Lambkin uses palmitin as a vehicle for the suspension of mercury for intramuscular injections in syphilis. He claims that it is non-irritant and non-toxic; it is not so easily oxidized as the other components of human fat, but is easily saponified and soluble in the human organism, and does not enter the circulation as a foreign body. It makes a more homogeneous preparation than any other, and its melting point can be raised or lowered with the greatest facility. The addition of pure absolute creosote and camphoric acid prevents pain, not only at the time of injection but that which usually comes on two to three days after an injection.

5. Separation of the acetabular epiphysis of the femur is a condition of not infrequent occurrence. Diagnosis is usually made after an x-ray has been taken for some trifling accident. Its relation to adolescent coxa vara is important. If a case of separated epiphysis with a history of injury is untreated, the deformity known as traumatic coxa vara results. Treatment consists in wrenching the bones into place under an anesthetic, and if this cannot be done the neck must be screwed or nailed to the epiphysis, the femur being rotated and abducted till the fractured surfaces are in apposition. The symptoms occur in the following order: (1) Slight limping and aching; (2) increased pain, sometimes preceded by slight trauma; and (3) deformity. These stages correspond to the pathological ones of (1) separation of epiphysis without vertical rotation; (2) rotation on vertical axis; and (3) coxa vara. The severity of the pain depends on the rapidity and extent of the rotation. The writer urges immediate skiagraphy of all cases of slight limp or aching about the hip joint in patients of 12 to 18 years.

6. Taylor concludes from his work on the opsonic index and agglutination tests in cerebro-spinal meningitis that a high opsonic index is pathognomonic of the disease, but that a normal index does not prove its absence.

7. Cuff, A. *Spontaneous Aneurysm of the Dorsalis Pedis Artery.*
8. *Morgan, H. de R. *The Bacteriology of the Summer Diarrhœa of Infants.*

4. Pringle gives the results of the use of stovain in 100 cases including 31 inguinal herniæ, 12 appendectomies and 6 major amputations. He injects in the second lumbar space, and waits till there has been a free flow of spinal fluid before injecting .04 to .06 gm. of stovain. The patient is in the sitting posture. After the canula is withdrawn, the puncture is covered with collodion and the table raised at the foot. It takes 5 to 15 minutes to get the effect of the drug. The highest incision he has made has been for umbilical hernia. Out of the 100 cases there was one death, which however was not necessarily due to the anesthetic. There were 7 partial and 15 complete failures to produce anesthesia.

6. Jordan urges the most extreme care among x-ray workers to protect themselves from the malign influence of the rays on the sexual organs. He suggests several schemes to enable the operator to work with safety and comfort.

8. Morgan in his recent researches on the bacteriology of summer diarrhea in infants has found a hitherto undescribed bacillus, which preponderated among all non-lactose fermenting bacilli. It differs from the bacillus of hog cholera of McFadyean, from the B. Enteritidis of Gaertner and the B. Dysenteriæ of Flexner. He believes that the type of summer diarrhea of infants in America is clinically and bacteriologically different from that in England. [J. B. H.]

The Practitioner.
June, 1907.

8. Hadfield, C. F. *The Treatment of Dropsy by Deprivation of Salt.*

2. At the end of 1906, Moynihan had operated on 114 cases of duodenal ulcer, with perforation in 11 cases. Out of 262 cases, 242 ulcers were found in the first part of the duodenum, usually on the anterior surface. In about 40% of his cases it was associated with gastric ulcer. He believes that in almost all cases of hyperchlorhydria the real trouble is gastric or duodenal ulcer. In 15 of his cases repeated and increasing hemorrhage was the cause of operation; this is a far more serious matter than hemorrhage from a gastric ulcer. In 7 of his cases gall-stones were present. The differential diagnosis of these two conditions is difficult. In the early stages where prolonged careful medical treatment can be carried out there is no need of surgical interference; if this cannot be done, he advises surgery from the start.

3. The pretuberculous stage of pulmonary tuberculosis may be roughly said to be that early stage at which the physical signs are indefinite and insufficient of themselves to justify a diagnosis of pulmonary mischief. They constitute a clinical picture which can only be recognized by experience. Over-attention to variations from the normal in the lung condition tends to exclude from consideration other broader and perhaps more significant symptoms and signs. The estimation of the length of time from the exposure to infection to the time of development of the first symptoms is an interesting and important but difficult task. In his cases this period averages three years. He could get decided evidence of infection in only 31% of 150 cases. The first symptoms are functional disorders, as, for example, loss of appetite, constipation, dyspepsia, etc. An evening pyrexia is very significant. Hemoptysis very often occurs with no physical signs. The result of coming to a "tentative diagnosis" so far as treatment is concerned amply justifies itself whether the real condition turns out to be tuberculosis, influenza or debility. The chief characteristic of the pretuberculous anemia is a muscular dystrophy affecting both voluntary and involuntary muscles. The bronchitis and "colds" of this stage are marked. Galbraith goes into the details of recent methods of diagnosis, such as wide variations of temperature, x-ray examinations, showing the small size of the heart, the ulnar reflex, examination with the thoracic perimeter, the tuberculin test and the opsonic index. The paper is an excellent recapitulation of this entire subject and is well worth reading.

4. In cases of amebic abscess of the liver it is found that weeks of fever with a slight leucocytosis precede the signs of pus. This is the pre-suppurative stage of amebic hepatitis. If this stage can be recognized a very important step will have been taken. The fever at this stage yields to large doses of ipecac, and thus the abscess stage is prevented. The writer cites various series of cases with and without dysentery treated with and without ipecac and gives the results. He believes it very important to try treatment with this drug before operating. [J. B. H.]

1. The intimate relation existing between general blood pressure, local renal circulation and diuresis is well recognized, but disturbances of these relations in nephritis are not so well understood. The effect of certain stimuli on these relations in health is known. Their action on the experimentally diseased kidney has been studied by Schlayer and Hedinger, and the action of such stimuli used as a functional test of renal activity in various forms of toxic nephritis (potassium chromate, mercuric chloride, cantharidis, arsenic and diphtheria toxin). Blood pressure was studied in these experiments by a mercury manometer, renal volume by an oncometer, and diuresis by an apparatus for estimating the number of drops of urine excreted in five minutes. Renal lesions were studied histologically. By this means Schlayer and Hedinger distinguish two types of nephritis, a tubular (potassium chromate and mercuric chloride) and a vascular (cantharides and arsenic). Diphtheria toxin produces a combination of the two types. In the tubular type in the earlier stages there is no change in the vascular contraction and dilatation of the kidney and there is an increased diuresis. Later, dilatation is decreased and finally stopped with cessation of diuresis. Contractibility of the renal vessels persists. In the vascular type disturbance of vascular contraction and dilatation appears early, and soon there is a total insufficiency of the renal vessels, with very slight excretion of urine. In the tubular type albumin and casts are present in considerable amount, while in the vascular type they are slight. Histologically demonstrable lesions are much slighter in the latter. These studies show that albumin excretion can take place in both glomeruli and tubules, while casts are formed in the tubules without any relation to the blood vessels. With severe vascular lesions decreased diuresis is always associated, but the converse is

not true. In acute vascular nephritis there is a decreased blood pressure.

2. Wandel by therapeutic experiment on chlorotic patients attempts to answer the question whether in chlorosis there is a deficient stimulation of the hematopoetic organs, or an inability for them to form hemoglobin owing to a lack of iron. Stimulation of the hematopoetic centers he seeks by sweating in the electric light bath. This increases the number of blood corpuscles, and in secondary anemia rapidly restores the blood to normal. In chlorosis, however, the increase in hemoglobin is very slow as compared with that obtained after giving iron. Consequently he believes the second of the two hypotheses best explains the disease. In chlorosis hydrotherapy is an adjuvant in treatment, but not a substitute for iron. Iron in some form is necessary for successful treatment, whatever its way of acting may be.

3. Arhythmia is divided into three groups: (a) Infantile type, (b) type due to extra systoles, and (c) arhythmia perpetua. In the latter there is complete and persistent irregularity in which the length of systole and diastole and the force of contractions vary and the normal rhythm is completely lost. This form is usually associated with a systolic venous pulse which does not depend on a tricuspid insufficiency, but on a primary auricular pause. The condition is more frequently associated with chronic myocarditis than with valvular disease and may occur without there being a break in compensation.

4. Heincke and Meyerstein have studied the relations between hydrops and salt and water excretion in experimental nephritis. They used rabbits and injected uranium nitrate or potassium bichromate to obtain renal lesions. Between the two there is a considerable difference in action, the uranium salt producing the more marked edema. As in man so in these animals the edema does not appear always to be produced in the same way. In the uranium rabbits edema seems to be the result of vascular lesions and may appear without much of a demonstrable anatomical lesion of the kidney. In the chromium rabbits, on the other hand, the edema is more the result of lesions of the tubular epithelium. In both, salt retention plays a part, but with uranium it has a minor rôle. The tubular epithelium appears to have a secretory action for salt.

6. Schmidt finds that perforation of softened anthracotic lymph nodes into the respiratory tract is not very uncommon about Dresden. Usually an aspiration pneumonia followed by pulmonary abscess or gangrene results. The diagnosis can be made when the associated pulmonary tuberculosis remains in the background. The diagnosis is to be based on the old age of the patient, the pulmonary condition beginning as a putrid bronchitis and developing into abscess or gangrene, localized pain or tenderness in the region of the manubrium sterni and the presence in the sputum of small bits of friable material which on microscopic examination show large particles of carbon pigment and various degeneration products.

7. Selling has studied by means of resonators and with a receiving phonograph the note produced by percussion of the lungs in normal and pathological conditions. This paper is concerned more with a theoretical consideration of the acoustics of the percussion note than with any practical application in diagnosis. [H. A. C.]

REVUE DE CHIRURGIE.

JUNE, 1907.

1. QUÉNU, E. *Separation of the Inferior Tibio-fibular Articulation.* (Continued article.)
2. *DESJARDINS, A. *The Technic of Pancreatectomy.*
3. *NICLOT, and ROMARY. *Gunshot Wounds (Armes de Chasse) in their Relation to Injection.*
4. *ALAMARTINE, H. *Tuberculous Hypertrophic Osteoarthritis.*
5. *DÉVÉ, F. *Hydatid Cysts of the Liver Containing Air.* (Concluded.)
6. *LE DAMANY, P. *Congenital Dislocation of the Hip.*

2. Desjardins describes a method of partial excision of the pancreas based on anatomical grounds. This can best be performed by excising the duodenum also. The various anastomoses necessitated by this procedure are well illustrated.

3. From various experiments Niclot and Romary conclude that a shot-gun wound should be considered and treated as though superficially infected. The skin should be cleaned with antiseptics. All exploration to remove shot should be avoided.

4. Alamartine calls attention to the fact that in hypertrophic osteo-arthritis and osteitis (the so-called syndrome of Marie) tuberculosis will be found as a cause in a much larger percentage of cases than is at present acknowledged. Further, in many cases a distinct family history of tuberculosis is present.

5. Hydatid cysts of the liver containing air may be divided as follows: (1) Cysts opening into a bronchus; (2) cysts opening into the digestive tract; (3) closed cysts; (4) cysts containing air after operation. Dévé has collected 57 cases of cysts of this sort. Several radiographs made with the body in varying positions are of definite aid in diagnosis. Wherever possible such cysts should be drained, as only a small amount of air will be absorbed after aspiration.

6. By a large number of statistics gathered from physicians, LeDamany finds that the frequency of congenital dislocation of the hip increases with the anthropological elevation of the race, attaining its maximum in the white female. This is in contradistinction to the rule governing all other congenital affections which are more frequent among the black races. [W. C. Q.]

Correspondence.

LETTER FROM PARIS.

(From Our Special Correspondent.)

AMATEURS OF PURE SCIENCE.

PARIS, July 9, 1907.

Mr. Editor:

"MY musical friend, at whose house I am now visiting, has tried all the owls that are his near neighbors with a pitch pipe set at concert-pitch, and finds they all hoot in B flat. He will examine the nightingales next spring." (GILBERT WHITE, *Natural History of Selborne.*)

The dear soul! And to think that the universe waited until the year of our Lord, 1771, before knowing that the English owl hoots in B flat! However, since the circulation of the blood in the human body was only discovered in the century before that, it is perhaps not a matter for surprise that facts of minor importance had to wait even longer. Let us hope that the musical gentleman really did live until the following spring, so as to settle that little question about the nightingales. Think of that old dry-as-dust sitting up during the beautiful spring nights of England, blowing on his wretched pipe, instead of listening to the sweet songs in the bushes that it was only his privilege to hear during a brief period each year. He reminds you of Murger's Latin quarter student, "*Qui à la place du cœur n'avait qu'un vieux bouquin.*"

This by way of preface to a few remarks on the amateur of pure science in general. This is a being that always fills me with wonderment; a man to admire, in a way, while you deplore his lack of practical sense; a man to whom you take your hat off, as you would to one vounteering for a forlorn hope, while at the same time you inwardly remark that you thank God you are not such as he!

There exists scattered all over the world, but probably more so on the Continent than elsewhere, a large army of these amateurs of pure science, men completely detached from the world, its interests, struggles and ambitions, often pure "solitaires" without families, living in and for their laboratories, on some miserable salary that just supports their physical wants; and who at certain intervals produce some abstruse and painstaking work that is of no use to anything or anybody, and that at the end of the year is rewarded by some learned academy by a medal or a prize.

Just take, for instance, the reports of the Société de Biologie here in Paris, and run over the titles of the papers presented; and then ask yourself the question what could have been the object in view of the men who devoted all this time and labor to the elucidation of this or that point. One man, for instance, will discourse on the mode of

termination of the motor-nerve filaments in the muscular fibrillæ of the quadriceps of the common house fly, *musca embêtans*. What practical result could he expect ever to come out of all this effort? for in this world the only effort that is of value is the effort that results in some advance to the welfare of our species.

Coming as I do from many generations of practical New England stock, I can comprehend nothing that is not practical; and when I look about me and see the quantities of matters of real practical interest to humanity that could very well stand a certain amount of thought and labor on the part of intelligent men, and feel that thereby the health, comfort and interests of humanity would be materially advanced, — it seems to me a great pity that all this mass of work on the part of these amateurs of pure science could not be directed into more profitable channels. For there is no disguising the fact that if it were feasible to calculate the amount of work put in by this class of society in the course of a year, it would be found to be very considerable indeed. When I look at their products, a yearbook of the Société de Biologie or of the Académie des Sciences, for instance, I can only think of one thing, a cemetery for the corpses of still-born infants, products of human energy destined to come to naught from the time of their inception.

Some indignant laboratory man will come back at me, no doubt, with the arguments on his side of the question: the practical results that *have* come out of the laboratory; that I take at best a narrow view of things; and that my ideals are low and merely utilitarian.

I have no idea of expressing disapproval of laboratory work in general; merely of what I call the amateur of science *pure*, that is, science for the mere love of science, without purpose or aim, science such as that of my hooter in B flat mentioned above.

Just take him as an instance. The amiable Gilbert thinks he has dropped onto something quite important, for he first reports the fact in his letter of Feb. 12, 1771, to the Hon. Daines Barrington, and then returns to the subject a second time in his letter of Aug. 1, 1771, to the same party, six months later, during which period he has had time to collect further data on this absorbing topic: "A neighbor of mine, who is said to have a nice ear, remarks that the owls about this village hoot in three different keys, in G flat (or F sharp), in B flat and A flat. He heard two hooting to each other, the one in A flat and the other in B flat. *Query:* Do these different notes proceed from different species, or only from various individuals? The same person finds upon trial that the note of the cuckoo (of which we have but one species) varies in different individuals; for, about Selborne wood, he found they were mostly in D; he heard two sing together, the one in D, the other in D sharp, who made a disagreeable concert; he afterwards heard one in D sharp, and about Wolmerforest some in C. As to nightingales, he says that their notes are so short, and their transitions so rapid, that he cannot well ascertain their key. Perhaps in a cage, and in a room, their notes may be more distinguishable. This person has tried to settle the notes of a swift, and of several other small birds, but cannot bring them to any criterion."

There, you see, is the amateur of pure science in all his perfection. He began with the owl, and was so fascinated by the interest of the pursuit (appetite comes while eating) that he went on to a number of other birds, at the risk of acquiring insomnia and that apparently common though to me mysterious disorder which English people designate as "a chill on the liver"! And all this to what purpose? *Faut-il, Seigneur, qu'il ait en du temps à perdre!*

Again, I know that the great German, Goethe, has said that "*es ist immer gut etwas zu wissen*"; and that deep thinkers all advise "a wide sympathy" in human affairs, "a broad-minded interest" in all about us. Still I think that there is a limit to that sort of thing, and that time and labor put into the elucidation of a subject merely for sport, for the pleasure of the chase, as it were, with no visible result at the end, is time and labor lost. The world in not one whit the better, in any conceivable way or shape, for knowing that the Selborne owls hoot in B flat, — when they don't hoot in some other key, sharp or flat!

In connection with Goethe's maxim, I was once called to see a patient here with a small subcutaneous abscess of the neck, and while attending to it I had time for a good deal of general conversation. He was a tall, spare Englishman of about fifty-five, evidently somebody, though I had no idea what; he might perfectly well have been either a superior officer, a distinguished surgeon, a leading divine, in fact, anything of rank you please. But two points struck me forcibly at the first visit: he was well posted in the relative merits of asepsis as opposed to antisepsis; and he knew all about the arguments in favor of operating in appendicitis during the first twenty-four hours, and, after the lapse of that period, of leaving it to get well as best it can. So I made up my mind by the end of my visit that this was some distinguished confrère in disguise, and that he was — well, excuse the language — pulling my leg. He ultimately turned out to be a celebrated judge, now a lord, who had found it profitable in his profession to know as much on all subjects as he conveniently could assimilate.

I was very much struck with the beauty of pure science once while attending a reunion of the Académie des Sciences here in Paris. This is the highest scientific body in France, composed of the leading men in all branches of science. To become a member of this body is the crowning step in all French scientific careers. Attend one of these meetings and you will see there gathered together all that France boasts of the very best.

Well, I went to see them, one day, and one tottery, aged gentleman, with a feeble, quavering voice, got up and addressed them on the order and place in which the buds and shoots develop on a certain plant during the growth of its initial spike; and while reading this document in his inaudible voice he turned his back frequently to his audience and drew on a blackboard tiny little diagrams which no one could see! This before a gathering of eminent surgeons, physicians, astronomers, chemists, mathematicians, physicists, etc. It was an extraordinary performance.

With the world filled with unsolved problems not only of a biological order but in all branches of knowledge, problems whose correct solution would be of immense benefit and interest to humanity, it is difficult to understand that these hooters in B flat can have the effrontery either to take themselves seriously and imagine they are accomplishing something of use, or that they should think that the world takes sufficient interest in their papers to read them when they appear in due season in the *comptes rendus*. What an appalling dust-bin must be the archival sanctum of such societies as the Biological, and others of the same class!

"Spectator."

PROFESSOR MENDEL'S GREATEST SERVICE TO NEUROLOGY.

Boston, July 26, 1907.

Mr. Editor: The obituary notice of Professor Mendel in this week's Journal omits any mention of his greatest service to neurology. One of the last acts of his life was to assist in preparing the number of the *Neurologisches Centralblatt* which contains his son's tribute to his memory and the regret of the publishers at the breaking of the associations of over a quarter of a century. The establishment and the successful management of the *Centralblatt* during all these years, before similar journals in other languages were even thought of, have made the neurologists of the world his debtor by giving them a full and careful summary of what was best in neurological literature. In addition to this Professor Mendel undertook the general editorial work of the *Jahresbericht über die Leistungen und Fortschritte auf dem Gebiete der Neurologie und Psychiatrie*, to which he also contributed the section on the organic psychoses. Although his volume (not "paper") on general paralysis which antedates the *Centralblatt* still remains a classic, the *Centralblatt* itself and the *Jahresbericht* will be his most enduring monument and a worthy memorial of a genial and learned teacher.

Yours very truly,

Philip Coombs Knapp, M.D.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED JULY 17, 1907.

KERR, J. W., assistant surgeon-general. Granted leave of absence for twenty days from Aug. 12, 1907. July 16, 1907.

MEAD, F. W., surgeon. Directed to proceed to Point Pleasant, N. J., for the purpose of examining keepers and surfmen of the Life Saving Service; upon completion of which to rejoin his station. July 16, 1907.

KALLOCK, P. C., surgeon. Granted leave of absence for seven days from July 15, 1907. July 12, 1907.

WERTENBAKER, C. P., surgeon. Directed to proceed to Ocean City and other points along the Chesapeake Bay, for the purpose of examining keepers and surfmen of the Life Saving Service; upon completion of which duty to rejoin his station.

STANSFIELD, H. A., passed assistant surgeon. Relieved from duty at Havana, Cuba, effective July 11, 1907.

BAHRENBURG, L. P. H., passed assistant surgeon. Granted leave of absence for seven days from July 15, 1907, under paragraph 191, Service Regulations.

HERRING, R. A., assistant surgeon. Granted leave of absence for eight days from June 30, 1907, on account of sickness. July 15, 1907.

KASTLE, J. H., Chief Division Chemistry Hygienic Laboratory. Detailed to attend the eleventh annual convention of the Association of State and National Food and Dairy Departments at Jamestown, Va., July 17–19, 1907. July 15, 1907.

CLEAVES, F. H., acting assistant surgeon. Granted leave of absence for six days from July 15, 1907, under paragraph 210, Service Regulations.

FOSTER, J. P. C., acting assistant surgeon. Granted leave of absence for twenty-seven days from July 20, 1907. July 16, 1907.

FOSTER, S. B., acting assistant surgeon. Granted leave of absence for six days. July 15, 1907.

SAFFORD, M. V., acting assistant surgeon. Granted leave of absence for four days from July 10, 1907, under paragraph 210, Service Regulations.

TOWNSEND, W., acting assistant surgeon. Granted leave of absence for seven days from July 14, 1907. July 12, 1907.

HALL, L. P., pharmacist. Granted leave of absence for seven days from July 16, 1907, under paragraph 210, Service Regulations.

NEVES, GEORGE, pharmacist. Granted leave of absence for 30 days from Aug. 10, 1907. July 11, 1907.

APPOINTMENT.

DR. LOUIS A. THUNIG appointed acting assistant surgeon for duty at Stapleton, N. Y.

RESIGNATIONS.

The resignation of Assistant Surgeon E. M. STEGER was accepted, by direction of the President, to take effect July 14, 1907. July 16, 1907.

The resignation of Pharmacist GEORGE NEVES was accepted to take effect September 8, 1907. July 11, 1907.

BOARDS CONVENED.

A board of medical officers was convened to meet at Baltimore, Md., July 24, 1907, for the physical examination of certain officers of the Revenue-Cutter Service. Detail for the Board: Passed Assistant Surgeon J. T. Burkhalter, chairman; Acting Assistant Surgeon J. LaB. Ward, recorder.

A board of medical officers was convened to meet at San Francisco, Cal., July 24, 1907, for the physical examination of certain officers of the Revenue-Cutter Service. Detail for the Board: Surgeon H. W. Austin, chairman; Passed Assistant Surgeon J. D. Long, recorder.

RECENT DEATHS.

DR. EDWARD J. GALLAGHER, of New York, was instantly killed, on July 21, by the collision of his automobile with a railroad train at a grade crossing at the St. Albans station of the Long Island Road, near Jamaica. His fiancée, Miss Helen Madigan, who was with him in the car, was so severely injured, as well as burned by a gasolene blaze which followed the collision, that she died shortly afterward in the Jamaica Hospital. Dr. Gallagher was graduated from Bellevue Hospital Medical College, in 1887, and at the time of his death was visiting physician to the House of Calvary and the Cancer Hospital.

DR. LEE MCELROY, a young practitioner, of Elizabeth, N. Y., died, on July 26, in the Alexian Hospital in that city, of whose visiting staff he was a member. He was a native of Bardolph, Ill., and thirty years of age. He was graduated from the Northwestern University, at Evanston, Ill., and afterwards served as interne in the Alexian Brothers' Hospital, in Chicago. He had been practising at Elizabeth for the past two years.

Original Articles.

COMPARATIVE TESTS FOR OCCULT BLOOD IN GASTRIC CONTENTS AND FECES, WITH ESPECIAL REFERENCE TO THE BENZEDIN TEST.

BY JOHN W. DEWIS, M.D., BOSTON.

From the Out-Patient Clinic of Dr. Joseph H. Pratt, Massachusetts General Hospital, Boston.

THE demand in recent years for a sure and convenient clinical test for minute quantities of blood or "occult blood"* (Boas[1]) has led not only to discovery of new tests but to the modification and improvement of the older methods. Formerly, aside from the Teichmann test which was of little clinical value, a macroscopical examination was the only means adopted to determine the presence of blood in the stools, and it is only within the past four or five years in this country that other methods have been more generally employed. Any one who has used more exact tests will have found that in many stools very considerable quantities of blood may be present and be imperceptible to the naked eye. Schumm[2] states that stools with a blood content of 5% and more are often passed by as blood-free, and that on a plentiful milk diet, free of meat, even a larger percentage may be unnoticed. The same is true in the examination of gastric contents when, in the presence of free hydrochloric acid, there may be no visible evidence of blood, and yet a distinct reaction for blood be obtained. When the stomach contents are first withdrawn the presence of moderate quantities of fresh blood may be plainly seen, but the hemoglobin, in the presence of the acid gastric juice, is soon broken up and a solution of hematin is formed, causing the pink or red color to fade or disappear; or where large quantities of blood are present, to assume a brown color. Both Kuttner[3] and Ewald[4] call attention to this fact, and the occurrence is illustrated by the following case of subacute alcoholic gastritis: A patient brought to the clinic a specimen of red fluid with a grumous sediment which he had vomited two days previous, — the blood tests were intensely positive. Five hours after ingestion of a glass of milk, a stomach tube with closed end was easily swallowed and 15 ccm. of mucoid opalescent contents obtained; no food elements were seen, and there was not the slightest *visible* evidence of blood, yet the guaiac, aloin and paraphenyldiamin tests were all clearly positive. Free HCl was present.

It is not the purpose of this paper to consider the clinical value of detecting occult bleeding already proved by many observers (as Kuttner[3] Boas,[1] Boas and Kochman,[5] Schloss,[6] Clemm[7] Hartmann,[8] Rossel,[9] Schmilinsky,[10] Petrachi[11] and Rütimeyer,[12] and in this country, Steele,[13 15 16] Steele and Butt,[14] Tileston,[17] White,[18] and Friedenwald and Rosenthal,[19]) but to show by the following review of statistics and a series of comparative tests the methods best suited for clinical purposes.

* Termed by Boas "occult bleeding" because blood is neither macroscopically nor microscopically demonstrable, but can be detected by chemical means.

TEICHMANN'S TEST.

It is more than fifty years since Teichmann,[20] working under Henle, after a long series of experiments, obtained hemin crystals, and demonstrated the process of their formation. Similar experiments on the blood had been independently carried on by Kunde[21] and Hunde,[22] and previously reported. Since that time Teichmann's hemin test has been, until recently, the chief method for detecting small quantities of blood. Hemin crystals, according to Hagar,[23] are produced in a blood dilution of 1 to 20,000; Thierfelder's analysis makes one part hemin correspond to about 162 parts of blood. It is not a sure test, nor convenient, and it is less delicate than other tests. Schumm[2] (p. 10) says that until 1902 he had frequently employed Teichmann's test, but could not recommend it for the detection of blood in stools as it sometimes completely failed, even when quite large quantities of blood were present, and in other cases he obtained a positive result only after many repetitions of the test. There seem to be fewer objections to its use as a test for blood in gastric contents.

SPECTROSCOPIC BLOOD TEST.

This method has long been employed to detect blood in solutions. But, as stated by Boas and Schmilinsky, the apparatus is too expensive and cumbersome for use by the general practitioner, and less delicate than the guaiac test. The cyanide of potassium test of Hofmann[24] and the hemocromogen test as employed by Hoppe-Seyler,[25] are probably the most delicate tests by means of the spectroscope. Jaworski and Korolwicz,[26] Schlesinger and Holst,[27] Schumm,[2] and Grünwald[28] also review the spectroscopic methods. Grünwald particularly advocates the cyanide of potassium test and gives the following table showing the relative delicacy of tests :

	In a Dilution of	
Weber's (his own results)	1: 2,000	(blood solution) positive
Benzedin	1: 150,000	" " "
Hemocromogen	1: 5,000	" " "
Cyankalium	1: 5,000	" " "

But, as shown below, we know that the guaiac test is more delicate than indicated in this table.

Schmilinsky (p. 2145†) gives a simple method of obtaining the blood spectrum by means of the hematoporphyrin method : a number of drops of stomach contents or feces, well mixed with water, are slowly added to a few cubic centimeters of concentrated sulphuric acid. If the solution is placed in a glass dish with plain parallel walls the spectrum can be easily recognized. The test is quite sharp and quickly carried out; if it is negative the guaiac test, which is more delicate, must be applied, so nothing is gained by its use.

† The principle, of course, is that of Hoppe-Seyler, and the sides of the vessel (known as the hematinometer) are 1 cm. apart.

GUAIAC TEST.

The guaiac test, next to Teichmann's, is the oldest clinical test devised for the detection of occult blood. Schönbein [29] discovered the test and established a majority of the facts relating to it; but at the same time His [30] determined many facts regarding the test, and a few years later van Deen [31] as the result of his experiments (published in 1863) proved the delicacy of guaiac as a test for blood, determined many of its limitations, and pointed out its value as a test in forensic medicine. Liman,[32] also, in this year (1863) reviews the work of van Deen and partially that of Schönbein. He made more than 50 applications of the guaiac test to various blood dilutions and other substances. In the past twenty-five years the results of all these experimentors have been many times tested and reaffirmed by various writers.

Schönbein showed that the iron of the blood was the means of transferring the ozone of the ozone-carrier (as (H_2O_2) to the tincture of guaiac. His (p. 213) remarked that the active substance of blood corpuscles, when dried or when a solution is heated to boiling, does not lose the quality of causing the blue color to appear; he heated a solution of blood corpuscles to boiling, then caused complete coagulation by adding a drop of acetic acid, and this coagulum, which was then washed with distilled water, still gave a blue color with guaiac and H_2O_2, and even the colorless filtrate gave a weak color reaction. His found that there was no difference between the activity of venous and arterial blood in causing a blue color on addition of tincture of guaiac and H_2O_2; but he found that no color appeared if the ozone bearer (Ozonträger) was first added to the blood solution and then the tincture of guaiac; but if to this mixture H_2O_2 was again added, a blue color quickly appeared. Schönbein (p. 213) found that pure blood serum caused no color change with guaiac, and washed fibrin only a slight reaction; bile and saliva gave an uncertain cloudy blue; chyle, fresh milk, casein (action destroyed on boiling), milk, sugar, epidermis, gastric mucosa, pancreas and liver substance, all gave a doubtful color; egg albumin, long macerated raw flesh, and fresh urine no reaction; fat and connective tissue, uric acid and urea a weak color.

Schönbein and van Deen both applied the guaiac test to a large number of metallic substances and the following are the chief preparations mentioned by van Deen: the oxide and sub-carbonate of iron gave negative results; the ferrous salts and sulphide of iron gave a slight degree of color reaction; the acetates and citrates and chlorides, particularly the latter, gave this reaction in more marked degree; the subacetate and sulphate of copper gave slight reactions similar to that of old blood; some of the reactions though not typical were sufficient to confuse; other copper salts, the red oxide of lead, coloring matters, as carmine and logwood, also sandal wood, all gave negative results.

In one of the many experiments with blood and guaiac van Deen found that when a portion of a three-year-old dried blood-cake (of calves) was mixed in water to a dilution of at least 1 to 40,000, the guaiac and old oil of turpentine still gave a positive reaction, though it was necessary to wait some moments for the blue color to appear; he found the test was equally sensitive for old or fresh blood. Liman [32] (p. 205) obtained no perceptible guaiac reaction in a blood dilution of 1 to 40,000.

It is surprising that, after so much experimentation with guaiac as a blood test, little mention was made of it till Vitali [33] published his paper in 1887. Then followed articles by Brücke [34] (1888) and Schuster [35] (1890). Vitali [33] found the test reacted to pus as well as blood. On account of the many exceptions to its use as a blood-test it had little clinical value till modified by Weber [36] in 1893. Weber found that by making an acetic acid ethereal extract, practically all the substances which may interfere with the test for blood are eliminated, particularly the preparations of iron, pus, saliva, milk and starch, or their action much weakened as in the cases of greens, spices and bile. The presence of bile in stools may obscure the trace of blue or green by brown shades when the amount of blood is small, and especially if bile is in excess. Schumm's method (see below) overcomes this objection. Brandenburg [37] found that when guaiac was added to pus it gave a blue color reaction without the addition of an ozone-bearing substance. Brandenburg found this reaction with pus was due to the nucleo-albumin which was precipitated by acetic acid, and that an acetic acid ethereal extract of *pure* pus gave no color reaction with guaiac; so that pus does not interfere with the blood test by Weber's method.

Besides the writers mentioned, many others have contributed to the knowledge of this test, including Kuttner,[3] Boas,[38] Boas and Kochman,[5] Schaer,[39] Hartmann,[40] Joachim,[41] Carlson,[42] Ewald,[4] and Mathieu and Roux,[43] and in this country within the past four years, Steele,[13] and Steele and Butt,[14] Benedict,[44] * Tileston,[17] White [18] and Cowie.[45]

Although Kuttner [3] had, in a measure, indicated the value of detecting small amounts of blood in stomach contents, Boas was the first to make general applications of the test for occult blood in affections of the gastro-intestinal tract.

The following are Weber's original directions: (1) A plentiful portion (about 5 gm.) of feces is rubbed up with water, (2) a portion of this mixture is treated with one-third volume of glacial acetic acid and (3) extracted with ether. (4) After clearing, a few cubic centimeters of the ether extract are poured off and to this are added about 10 drops

* Benedict's modification of the guaiac test consists in adding to about 2 to 5 gm. of feces (diarrheal consistency) an equal amount of gasoline, then add about 1 ccm. fresh tincture of guaiac and an equal amount of old oil of turpentine. If blood be present, the gasoline, (which rises above the emulsion of feces, guaiac and turpentine) is colored green or blue according to the amount of hemoglobin present. Benedict claims for the test avoidance of delay and the spurting incident to the ether acetic acid extraction. The ingredients may be added in any order. The same objections, however, obtain with this test as with the original van Deen test.

of tincture of guaiac (see below) and (5) 20 to 30 drops of old turpentine. If blood be present the mixture turns to a blue-violet; if absent, a red-brown, often with a tinge of green. The reaction is more plain if some water is added and the color extracted with chloroform.

Cowie [45] has modified Weber's test by adding an equal amount of distilled water to the acetic acid ether extract, and thoroughly shaking, before adding the guaiac, and claims for this method a greater delicacy than any other modification of Weber's test; *e. g.*, Weber, by guaiac, obtained a positive reaction for blood in stools after ingestion of 3 gm. of blood, while Cowie was unable to verify this by Weber's test, yet with his "water modification" he was able to get a *distinct reaction after the ingestion of 0.5 gm. of blood.* Cowie, like Boas, adds a few granules of powdered guaiac to the ether extract, instead of preparing the customary guaiac tincture; when the guaiac is dissolved, the oil of turpentine is added.

In the comparative tests given below, the following method was employed:

1. About 5 ccm. of liquid gastric contents or 3 gm. of feces (the feces should be thoroughly mixed and made fluid by rubbing up with a little water) are mixed with one-third the quantity of glacial acetic acid.

2. Extract with about 10 ccm. of ether. To avoid the emulsifying action of ether, instead of shaking the tube, it should be slowly inverted several times.

3. *A piece of clear brown gum-guaiac about the size of a cherry is crushed and then dissolved in a test tube half full of alcohol (or ether, see below). This tincture should assume a light sherry color. Green oxidized portions must not be used.

4. To perform the test, about ½ ccm. of the guaiac tincture is added to about 5 ccm. of the acetic acid ether extract and to this 1 ccm. of a 3% peroxide of hydrogen (the usual commercial strength) or an equal amount of old oil of turpentine. (The H_2O_2 may be added to the tincture of guaiac first, when, if the tincture is strong, it may turn milky, but this is clarified on addition of the ether extract. This procedure serves as a control on the guaiac.)

In the presence of blood, a blue color quickly develops, which deepens, and in two or three minutes gradually fades to a pale blue and disappears; in the case of feces the disappearing color is sometimes a faded green. In fecal extracts, also, various shades of purple, purple-brown or red-brown frequently replace the blue, and with small traces of blood even a green shade. This green shade may never result from pure blood solutions, but I am convinced this sometimes occurs with fecal extracts, as I have seen cases where only a green shade occurred with the guaiac when the benzedin and paraphenyldiamin tests were clearly positive. As much difference of opinion prevails as to what colors, other than shades of blue, result from the presence of blood, shades of green should not be considered positive when a more delicate test is negative. When peroxide of hydrogen is used two layers form and the color reaction appears in the upper ether layer. H_2O_2 seems to give a somewhat quicker reaction and Boas found it more delicate. Oil of turpentine may mix with the ether extract, the color appearing throughout the mixture, but it usually settles to the bottom where the color appears. It was suggested by Schmilinsky [10] (p. 2146), and recently by Cowie,[45] that a color scale may be arranged so that the guaiac test could be used quantitatively, but the writer believes that color changes can only be used in a rough and general way to estimate the quantity of blood, and, as Clemm [11] (p. 377) states, such a scale is inconstant and not worth the tax on the judgment.

Should an emulsion form in making the ether extract it can be broken up, as pointed out by both Schmilinsky [10] (p. 2146) and Schumm [2] (p. 19), by adding a few drops of alcohol and giving the tube a few turns. The latter author claims that Boas's [7] warning that alcohol itself may cause color changes cannot be accepted, as in 1,000 applications of the test he used strong alcohol many times for this purpose and never noted this occurrence.

If the stools contain much fat it is better first to extract with ether, as recommended by Boas and Rossel,[9] before making the acetic acid-ether extract, as the guaiac reaction is thus made clearer. (There is no danger of losing blood, as hemoglobin in a neutral or alkaline medium is not absorbed by ether.) If there is much hydrobilirubin or vegetable coloring matter present, the writer has found the guaiac test much improved by first extracting with alcohol-ether (equal parts), instead of ether, which removes not only the greater part of the free fat and fatty acids but much of the coloring matter as well but not of the blood. (See also Schumm's method below.) Boas, White and Cowie believe the fat extraction is not often necessary.

When turpentine is used as the oxidizing agent it should be perfectly pure and clear (as Mercks) and before ready for use should be exposed to the air in an open dish and in a dark place for at least a month; afterward it should be kept in a bottle uncorked, or only lightly protected with cotton. It should not be left in strong sunlight, for Schumm [2] (p. 20) has seen turpentine thus treated give an intense blue with the plain tincture of guaiac, and I have seen such a specimen give a tinge of green-blue with guaiac.

Guaiac resin for testing purposes should be clear brown or wine color. A large piece 4 or 5 inches through (if possible) should be obtained, and a clear piece broken off when needed for use. Any oxidized (green) portions should be thoroughly removed, as these without the presence of blood may give color reactions; and for this reason guaiac, for testing purposes, should never be kept in the powdered form, as every particle becomes oxidized and untrustworthy for blood tests. Guaiac may be dissolved in either alco-

* As the following tests were begun by Weber's old method it was continued throughout, but the method used by Boas of adding a few grains of fresh guaiac directly to the ether extract and then adding the oxydising agent is fully as delicate and more simple.

hol or ether. It dissolves more readily in alcohol and is better for immediate use — it should be prepared about every hour. If a solution of guaiac is to be kept on hand, an ethereal tincture must be made, as this remains active for months.

The writer has not found the ether solution as satisfactory as the fresh alcoholic tincture, and the green residue which forms around the rim of the bottle may be a source of error in the former. The best method, as already mentioned, is to add a few bits to the ether extract with each test.

It is customary, before testing for occult blood in the stools, to place the patient on a special meat-free diet. Sometimes, however, it is important to make occult blood tests without any change of diet. It is thus necessary to know how much and what kinds of meat will usually give a positive reaction.

It is generally stated that red meats* in moderate quantities, eaten once daily, will sometimes give positive guaiac, and that cooking, though it does not prevent, lessens this reaction, and also that fish, fowl and ham do not give a positive test even if eaten in considerable quantity. Eggs never interfere with the test.

I have often examined stools of patients who had been on a mixed vegetable and meat diet, but never obtained a positive reaction by Weber's test in any case in which blood was absent. This agrees with Cowie's statement (p. 412) that an ordinary meat diet seldom if ever causes a reaction for occult blood. Cowie (l. c.), however, obtained a clear, positive guaiac reaction after the ingestion of 10 gm. of scraped raw meat, but no reaction when smaller amounts than 10 gm. of scraped raw meat had been ingested. (Further meat experiments under benzedin.)

As to the action of the guaiac test on crude drugs, the various preparations of iron, etc., probably little can be added to what was stated by Schönbein and van Deen and Liman 50 years ago; but the acetic acid ethereal extract of the stools prevents all drugs, probably, from interfering with the guaiac test for blood, and Weber [36] (p. 443) himself found of 67 medicines administered in various combinations to patients, that the acid ether extract of stools of these patients gave no action with the van Deen test. By the same method stools gave negative results after ingestion of milk; the ether acetic extract removed cause of error in presence of milk, pus, saliva or spices; and greens or bile caused less confusion when van Deen's test was performed by Weber's method.

The blue shade one obtains by the action of the guaiac test on Blaud's mass and on the tincture of chloride of iron very quickly disappears, though it is very like that produced by old blood. When Blaud's mass is treated with acetic acid, water added and shaken with ether, the ether extract gives no reaction with guaiac. I have many times applied Weber's test to stools which were black through administration of Blaud's pills, the dose often being 30 gr. daily, and in the absence of blood no positive action was ever obtained. Steele and Butt [14] found, also, that ferric carbonate, 30 gr. daily, and ovoferrin and peptomangan in daily doses of 1½ oz. failed to give a reaction similar to blood by Weber's test. It is safe to consider that *no* drug in therapeutic doses will give a reaction by Weber's method which may be confounded with blood. The delicacy of guaiac as indicated by various writers is given in the following:

		In 1 gm. of Stools * with Blood Content of	
Boas & Kochman	+ guaiac	0.0008	gm.
Schloss (p. 275)	+ „	{ 0.0008	„
		{ 0.0006	„
Hartman (p. 51)	+ „	0.00005	„ to 0.00001
Cowie (p. 419)	+ „	0.00035	„
Clemm (p. 377)	+ „	0.001	„
Schmilinsky (p. 2146)	+ „	0.01	„

+ equals positive.
* Or stomach contents.

Schloss (l. c.) was unable to confirm Hartmann's results either with guaiac or aloin, though Cowie [45] (p. 422) is inclined to believe the results of all correct. Schumm and Remstedt [52] (p. 993) obtained a barely positive guaiac solution of blood in water of 1 to 100,000; when 8 ccm. of the solution was used.

Schumm's [2] (p. 26–29) modification of Weber's test is performed in this way: About 4 gm. of feces (portion, size of walnut) is thoroughly rubbed up in a glazed porcelain mortar with 30 ccm. of alcohol-ether (equal volumes); the contents are then transferred to a clean coarse filter placed in a funnel (the filter should be unplaited and about 12 cm. in diameter); the residue in the cone is again treated with alcohol-ether (30 ccm.) and assisted in running through by stirring with a glass rod; when the filtration is completed some plain ether is poured over the filter and stirred as above, and when the ether has filtered off the residue is washed once more with ether. This process, in a *neutral* or *alkaline* mixture, usually removes the coloring matter, neutral fats and free fatty acids (soaps are not removed by neutral alcohol-ether), and it likewise removes the water present. Four cubic centimeters of glacial acetic acid are next added to the residue on the filter and gently but thoroughly worked through by means of the glass rod. Then 4 ccm. more of acetic acid are added and the stirring repeated, and when a greater portion of the acid has drained off, the combined acid filtrate is again poured over the cone and allowed to thoroughly filter. A number of cubic centimeters of the acetic acid filtrate is diluted with two or three times its volume of ether, and to this is added a half volume of distilled water, and the mixture shaken. If separation does not occur, add some alcohol, or ether, or water. The acetic acid ether extract is now tested in a thoroughly clean and dry † or alcohol-washed test tube. In the presence of hematin there appears in a short time a more or less clear violet-blue, red-violet or green-blue. Another portion of this extract may be used for spectroscopic examina-

* See experiments under benzedin.

† Cowie [45] insists on dry test tubes, as both he and his assistant, Dr. Roche, have obtained a positive guaiac (clear blue) when dry test tubes were used, and a negative test with the same specimen when tubes were not dry.

tion. In the case of liquid stools the procedure is the same, only a larger amount is taken and stirred up with about four times the quantity of alcohol-ether. If the stool is acid in reaction it is first treated with a number of drops of concentrated sodium carbonate solution, and then with the alcohol-ether.

Schumm claims great delicacy for his method. The writer has made few comparative tests with this process, but in the cases where tried, the colors were not only more clear and intense than with the guaiac test by Weber's method, but likewise when other test-agents, as aloin or benzedin, were used. The respective color changes were greatly enhanced when an extract of the specimen was made as directed by Schumm. Were it not a time-robbing procedure, Schumm's method would meet about all the requirements for a clinical test.

ALOIN.

Aloin was first described as a blood test by Klunge [46] twenty-five years ago, later by Rossel [9] and then by Boas, [47] Koziczkowsky,[48] von Torday,[49] Petrachi [11] and others.

For a time it seemed that aloin might displace guaiac because of its greater delicacy and reliability. In the past two years, however, it has been less recommended and some recent writers, as White and Cowie, have concluded from their experience that it is probably less delicate than the guaiac. Koziczkowsky obtained a positive aloin reaction in a mixture of 0.025 gm. of blood with 2 gm. substance and Cowie [45] (p. 415) obtained positive aloin with 0.02 gm. blood to 1 gm. of feces, and a questionable reaction with 0.005 gm. to 1 gm. of feces.

The preparation of the material for the aloin test is in all particulars the same as for the guaiac test. Oil of turpentine is better than H_2O_2, inasmuch as the reaction is more clear. To prepare the aloin solution, a portion of the powder (a good preparation, and the one used in these tests, is that of Parke Davis) is placed in a *clean* dry or alcohol washed test tube — sufficient to fill the bottom of the glass — and to this is added about 10 ccm. of 75% alcohol (aloin is scarcely soluble in ether, only about 1 to 500); when the solution becomes yellow it is ready for use. The test is then performed throughout as with guaiac, using the same proportions of reagents. Aloin solution should be made fresh, as after standing about half an hour it usually assumes a pink or slightly red color which is increased on addition of old turpentine.

The color change in a positive reaction is a pink or slight red to deep cherry red, or, in extract of stools, a red wine color. The color reactions are not as prompt as with guaiac and in the presence of only small amounts of blood the red color is not distinct for ten or twelve minutes. If the color only appears after fifteen minutes or more it should not be considered positive, as this sometimes occurs in the absence of blood. By adding a drop or two of chloroform the appearance of the color is hastened.

When the aloin solution, ether extract and oil of turpentine are mixed, by lightly shaking, the aloin solution usually sinks to the bottom where the color changes occur, but sometimes, as pointed out by Koziczkowsky (p. 1199) and Steele, the mixture becomes uniform, particularly if the aloin solution is made with strong alcohol (95%).

Ninety-eight occult blood tests were made with aloin and compared with an equal number of guaiac tests performed as suggested by Weber. Fifty-one of these comparative tests were made in stomach contents, and in three of these cases, in which the guaiac test was negative, the aloin test gave slight red color in five to fifteen minutes, and in each of these three cases the phenyldiamin test was positive. On the other hand, in a case of hyperchlorhydria with free HCl 0.26%, the guaiac test gave a slight blue, while the aloin test gave only a very slight pink, not distinctly positive (in this case the paraphenyldiamin was positive and likewise the benzedin). In another case the guaiac test gave a slight *red*, the aloin a slight pink in about twelve minutes, which did not increase, and the paraphenyldiamin was slightly positive. In one specimen of urine the guaiac test was doubtful (slight green tinge), a pink color appeared with the aloin and the paraphenyldiamin was positive. In the other urinary tests the guaiac and aloin agreed, except in one specimen in which the guaiac test (slight tinge of blue) as well as the phenyldiamin were positive, the aloin was completely negative. In two specimens out of forty-seven stools the guaiac test was negative, while the aloin gave a slight pink and the phenyldiamin was positive; in the remaining tests there was no discrepancy between the aloin and guaiac tests. The above results indicate that the guaiac (Weber's modification) and aloin tests are about equally delicate. (Further comparisons under phenyldiamin and benzedin.)

PARAPHENYLDIAMIN TEST.

A new and very delicate reagent for detection of occult blood has recently been introduced by Boas.[50] It was originally employed by Storch [51] in detecting pasteurized milk. The reagent consists of a very dilute solution (about 1 to 200) of paraphenyldiaminchlorhydrate with the addition of peroxide of hydrogen. With unheated milk the reagent gives an indigo blue, and the whey, as it separates, shows a violet and brown; in pasteurized milk the test gives a blue-gray color.

This test with certain modifications has been found by Boas a reliable and more delicate test for occult blood in feces than guaiac or aloin, but not so sensitive as benzedin. He states that for months he used it exclusively as a blood test, but believes the other methods should be retained as control tests in cases of doubt.

To perform the test according to Boas the stomach contents or feces are prepared much as with the aloin and guaiac tests, except that a smaller amount of acetic acid, about 20 drops, is added to the contents and extracted with ether as in the guaiac test; to 2 or 3 ccm. of this ether extract add 1 or 2 drops of a very dilute solution

(1 to 100) of a paraphenyldiaminchlorhydrate; to the mixture is added 1 ccm. of a half normal alcoholic potassium hydrate solution, and then 10 to 15 drops of a 3% H_2O_2. Upon slight shaking there appears almost momentarily in the bottom of the reagent glass a characteristic olive green (or blue-green) color, but especially characteristic is the olive green ring between the layer of ether and peroxide of hydrogen; the upper layer shows a more or less violet color. The green color is very transitory and, according to the blood content, quickly changes into a more or less deep violet. In the absence of blood the green color is either very faint or does not appear at all. If the stools are deeply tinged with bile or hydrobilirubin, they should first be extracted with alcohol-ether.

Following the directions of Boas, I applied this test to 103 specimens of gastric contents, stools and urines, at the same time making comparative tests with both guaiac and aloin, and in 43 of the specimens additional comparisons with benzedin. In no specimen where I obtained a positive reaction with either Weber's or the aloin test did I fail to get some degree of reaction with the phenyldiamin. In 11 of the cases where the latter was positive, Weber's test was negative, and in 7 of these the aloin test was negative. In a majority of these 11 cases the transient green ring, which Boas terms "extraordinarily characteristic," was absent, and in such cases a diffuse light green tinged with yellow appeared, quickly changing to a weak dirty brown or washed-out violet. I have considered as negative those reactions of phenyldiamin where no green shade was discernible in the beginning of the color changes. In stomach contents less discrepancy was found between the results of this test and those of aloin and guaiac than was the case in feces. Almost invariably when the phenyldiamin gave a positive reaction with gastric contents, the guaiac gave a clear blue and the aloin a distinct red.

The phenyldiamin test was never positive when the benzedin was negative, but it was negative six times when the benzedin was positive.

Schumm and Remstedt [52] have recently modified the procedure as carried out by Boas in the following way:

To the fluid under investigation are added only 2 drops of a 1 to 200 solution of paraphenyldiaminchlorhydrate, then 1 ccm. of about one half normal alcoholic potassic hydrate, then 1 ccm. of a 3% peroxide of hydrogen, and last of all are added a few drops (about five) of a dilute acetic acid. A newly prepared watery solution of freshly defibrinated human blood tested in this way shows in a moment an olive green color which gradually turns to brown red. In such a solution these writers found this test to be somewhat more delicate than the guaiac, and claim they were able to determine blood when in a watery dilution of 1 to 100,000 when 8 ccm. were used; on the contrary, if the acetic acid was added before the potassium solution the test failed in a blood dilution of 1 to 40,000 — no greater than the delicacy of the guaiac test, determined long ago by van Deen.[31] Schumm and Remstedt [52] never obtained a positive reaction in the stools by means of this test when Schumm's modification of Weber's test was negative or only suggestive. I have made no systematic comparison with this modification of the phenyldiamin test, but the test is delicate and it might be preferred to Boas's method, if only on account of the readiness with which the color changes are detected at the *top* of the solution. There is no ring formation, but in very minute quantities of blood a light green color almost immediately appears and gradually diffuses toward the bottom of the tube, and in the meantime the various shades of violet (as described above) have begun to appear. Schumm and Remstedt (p. 994) mention that in weak dilutions of blood the olive green may not appear, but only a red color. This is easily demonstrated in a watery solution of blood.

BENZEDIN TEST.

Benzedin was first described as a color test for blood by O. and R. Adler [53] in 1904, and is the most delicate of all the clinical tests for occult blood. Of the many chemical combinations (amido bodies, phenols, amido acids, naphtholine and diphenyl groups) with which they experimented, they found that benzedin, of the diphenyl group (H_2N-C_6H_4-C_6H_4-H_2N), in a saturated alcoholic solution, and with the addition of peroxide of hydrogen, determined the presence of blood in a dilution of 1 to 100,000 (0.001%). Schumm, however, found the limit of delicacy 1 to 200,000, when he used 8 ccm. of a fresh watery dilution of human arterial blood. It would detect 0.00004 gm. of blood. The guaiac test under equal conditions he found required eight times this strength of blood solution to give a reaction (detecting only 0.00032 gm. blood). He claimed the delicacy of the reaction depended upon the quality of the benzedin used; he employed Mercks "benzedin purissimum," but he had obtained *commercial preparations of "benzedin puriss," which were not so delicate as the guaiac test.* Schumm's results are easily verified. I have found that fresh human blood (hemoglobin 100%) in a dilution of 1 to 200,000, by volume, gives a clear pale green, with an acetic acid solution of benzedin and H_2O_2 in one minute, turning to a pale red in 8 to 10 minutes. If the blood solution is first heated to boiling and the benzedin reagent added while the blood solution is hot the color changes are very rapid, almost instantaneous, but the green color is not so evident, and the red shade appears within half a minute. If the blood is first treated with glacial acetic acid or HCl and then diluted, the color changes seem not so distinct as with pure blood solutions, yet gave a positive benzedin in a dilution of 1 to 175,000. Boiling the acetic acid blood solution lessens the power to cause color changes. Siegel,[54] and Schlesinger and Holst,[27] and Schumm,[55] also review the subject of benzedin and report their investigations, but Schlesinger and Holst materially modified the test recommended by A. and O.

Adler and gave it a distinct clinical value, which the original test did not possess.

The Adlers [53] employed benzedin as follows:

I. For urine, 10 or 15 ccm. are treated with a half volume of acetic acid and extracted with ether. On adding to the ether extract some saturated alcoholic solution of benzedin, with peroxide of hydrogen, the usual green color appears in the presence of hematin.

II. For feces, a small quantity is mixed with some water and to 3 ccm. of the unfiltered mixture is added 2 ccm. each of freshly prepared benzedin solution and peroxide of hydrogen, and three or four drops of glacial acetic acid. The presence of blood causes an intense green.

These authors, although they point out that certain oxidized ferments (indirect oxydases) in the presence of peroxide of hydrogen can be destroyed by boiling, do not mention this procedure in their directions.

Schumm [2] (p. 14) in applying the test to feces, according to this method found the reaction too delicate for clinical work.

Schlesinger and Holst, by modifying the original test, overcame the extreme sensitiveness and yet kept it beyond the delicacy of all other tests for occult blood in feces. Their method is as follows:

I. An approximately saturated solution of benzedin is made by adding a knife-point full of benzedin to about 2 ccm. of glacial acetic acid in a *clean* test tube; shake and set aside; the benzedin soon becomes dissolved. The solution is better if made fresh, though it is active after many days.

II. A piece of feces about the size of a pea is stirred up with a clean glass rod in a test tube about a fifth filled with water (test tube about 10 cm. long). The tube is then lightly closed with a stopper and the mixture brought to a boiling point over the flame. (The boiling destroys the activity of the enzymes.)

III. About 10 or 12 drops of the concentrated acetic acid solution of benzedin (I) is now poured into a clean test tube and 2½ ccm. to 3 ccm. of a 3% solution (ordinary commercial) hydrogen peroxide. A reagent is thus prepared which will not only serve as a control on the chemicals, but likewise on the reagent glasses.

IV. To perform the blood test we pour into the reagent (III) one to three drops of the boiled feces mixture (II) after lightly shaking it.

In the presence of blood there develops a beautiful green, blue-green or blue. The greater the blood content the more predominant is the blue. The appearance of the color-change in a case where the aloin test would be positive occurs in a few seconds, while in the presence of only a slight amount of blood ¼ to ½ minute is required. The time varies, but Schlesinger and Holst [28] state, and it is easily demonstrated, that even in the case of minute traces of blood the beautiful green color always appeared within two minutes. (Further description of color changes in Table I a.)

Following the modifications of Schlesinger and Holst [28] I have made 107 applications of this test (stomach contents, feces and urines), nearly all of which were in comparison with the aloin, guaiac and phenyldiamin tests. (In all the experiments I used the benzedin purissimum of Merck, Germany.) It is also important that the H_2O_2 should be pure, as I have found two preparations of peroxide of hydrogen which invariably gave a green color when added to the benzedin solution alone. "Dioxygen" of the Oakland Chemical Company and H_2O_2 of Parke Davis do not cause a green color with a pure solution of benzedin in glacial acetic acid.

In 36 of the specimens (gastric contents and feces) all four tests were applied to each specimen, making in all 161 applications (as in 17 of the specimens the benzedin test was applied both before and after boiling). In 12 of these series the results were uniformly negative with all the tests, five of the specimens were stomach contents, 7 were stools, obtained when the diet had been meat-free for at least three days. (These results demonstrate the importance of a negative benzedin test, and the amount of time it is possible to save in routine work where benzedin is applied first, as the whole test, including the preparation of materials, can be performed within two minutes.) In the gastric contents of one case, where the benzedin and phenyldiamin were distinctly positive the aloin was negative, but the guaiac showed a slight green developing in less than a minute, then disappearing; but in two specimens of stools the benzedin, phenyldiamin and aloin were positive, while the guaiac was negative. In one of these cases the aloin became a light red wine color at the end of 15 minutes, in the other a slight red in 10 minutes, and in this case the aloin and guaiac tests were repeated three times.

In 32 specimens of gastric contents the benzedin test was negative in 16. In 6 of this series the test was *positive before* boiling and *negative after* boiling the contents. This may show that enzymes * as secreted and under certain condi-

* In connection with these examinations of the gastric contents, the benzedin test was applied to the following preparations:

\+ = positive.
— = negative.

Preparation.	Age of Specimen.	How Treated.		Benzedin Test.
From one manufacturer:				
Scale and powdered pepsin.	Three years old.	Not boiled.	—	
Scale and powdered pepsin.	Fresh from manufacturer.	Not boiled.	—	
Pancreatic powder	Fresh from manufacturer.	Not boiled.	+	
Pancreatic powder.	Fresh from manufacturer.	Boiled.	—	
Pancreatic powder.	Fresh from manufacturer.	Not boiled.	—	With acetic acid ether extract.
Essence pepsin.	Fresh.	Not boiled.	—	
From another manufacturer :				
Peptonizing powder (from tubes)	Fresh.	Not boiled	+	Deep green blue.
Peptonizing powder (from tubes)	Fresh.	Boiled.	+	Distinct green.
Peptonizing powder (from tubes)	Fresh.	Not boiled.	+	Distinct clear green with acetic acid ether extract.
Peptonizing powder (from tubes)	Fresh.	Boiled.	—	With acetic acid ether extract.

tions give a positive benzedin. In these cases the green color reaction was usually very light, however, and slow in appearing, though usually within two minutes. The tests were carried on side by side and six drops each were used of boiled and unboiled contents. When 1 ccm. or 2 ccm. of boiled contents are added to the reagent a light green may develop in cases where 2 or 3 drops cause no color change. The test may be negative in *unboiled* gastric contents not only when HCl is absent, but when the free HCl content is high.

In 22 specimens of stools 10 benzedin tests were negative and the remainder positive. No definite green color change was found *before* boiling that was absent *after* boiling the specimen, but in nearly all the 10 negative tests color change was wholly absent without boiling, proving that enzymes seldom, if ever, interfere with the benzedin test in stools.

Stools which are suspected of containing blood, but give a negative blood test, should be well mixed and again tested, as a stool may contain portions *passed at the same time*, one of which will give a strong positive blood reaction by all blood tests, and another portion give a negative result with the benzedin as well as all the other tests. Such an occurrence was illustrated in the case of a patient (a woman fifty-two years old) seen with Dr. J. B. Thornton, and presenting a group of symptoms which suggested gastrostaxis* or gastro-enterostaxis. At first the stools were composed of soft and unformed masses, dark blue, or black, then becoming tarry, or very dark. On the fourth day, after sudden cessation of all symptoms, the patient passed a stool which gave both negative and positive blood tests. In this formed stool one portion was brown and gave an intense positive reaction by aloin, guaiac, phenyldiamin and benzedin. Other parts were light yellow (as seen after milk diet), and portions taken from the center of these light colored masses repeatedly gave a negative result with the benzedin, and with all the other blood tests. In some of the masses there had been a slight admixture, giving positive benzedin reaction and perhaps a slight reaction with some of the other tests. This seemed to be such an unusual occurrence that a great many tests were made at different times (and with care) for confirmation. Why the benzedin test could be negative in such a case as this, when, as has been stated by Grünewald[28] (p. 110), a positive test with benzedin was obtained in the stools 2½ *days after ingestion* of a ham sandwich, seems quite inexplicable. Schlesinger and Holst,[27] however, obtained by their method a negative benezedin reaction in stools in one case 60 hours and in another 36 hours following the ingestion of meat, though it was always positive within 24 hours, and in one case it gave a positive reaction 44 hours following the ingestion of 0.5 gm. of blood.

Experiments 1 and 2 indicate the results of the benzedin and guaiac tests when applied to normal stools, after the ingestion of various foods, and the increase in delicacy of either test when applied to the fecal extracts prepared according to Schumm.

EXPERIMENT No. 1.

Day.	Food Eaten.	Time of Stool.	Adler's Benzedin test with Schlesinger's and Holst's Modification.	Benzedin with Schumm's.	Weber's Test.	Schumm's Modified Weber's.	Aloin with Schumm's Extract.
21st and 22d.	Hearty evening meal of very rare roast beef for two days, other meals meat free.	No examination of stool on these days.					
23d.	Food during day: 3 eggs, salt codfish and cream, potato, bread, butter, oatmeal, tea, coffee.	Morning stool.	Strongly positive, specimen unboiled. Positive, specimen boiled. (*a*).		Positive (*b*).		
24th.	Eggs, oatmeal porridge, cream, milk, bread, butter, coffee.	Morning stool.	Positive, unboiled. Positive, boiled.	Intensely (*c*) positive.	Negative.	Positive (*d*).	Positive (*e*).
25th.	Oatmeal porridge, 1 egg, fish cakes, fresh mackerel, cream, milk, bread butter, coffee.	Morning stool.	Positive, unboiled. Negative, *boiled.*		Negative.	Negative.	Negative.
26th.	Breakfast, oatmeal porridge, few baked beans.	Morning stool lost. Stool at 3 P.M.	Negative, *unboiled.*	Strongly positive (*f*).	Negative.	Negative.	Negative.

Preparation.	Age of Specimen,	How Treated.		Benzedin Test.
Holladin.	Fresh.	Not boiled.	+	Strong blue with green tinge.
Holladin.	Fresh.	Boiled.	+	Color diminished, more green than blue
Protonuclein.	Fresh.	Not boiled.	+	
Protonuclein.	Fresh.	Boiled.	—	
Takadiastase.	Fresh.	Not boiled.	—	

It is difficult to show that some of the + reactions with these specimens were not due to blood. We should also expect a positive reaction to any considerable amount of enzyme powder that was active *in vitro*, but this was not the rule; and it may be that the enzymes which yield a positive reaction with benzedin are not always present or active in the commercial preparations.

* H. Wale White: The Lancet, London, Nov. 3, 1906, p. 1189. *Idem.*, Jan. 12, 1907, p. 126.

(*a*) Color change, intense green in three quarters minute, in one to two minutes green changing to black, in three minutes black color has changed to claret-red and no further change in fifteen minutes. On adding more feces solution, claret-red returns through black to green, back through black to red. With the boiled specimen, the same changes occurred as above, only the colors were much less intense.

(*b*) The color change was a light green with red brown in one half minute, green and red disappeared and left a brown which faded.

(*c*) The color change was a clear and intense green with the ether acetic acid extract (Schumm), and with the straight acetic acid extract (Schumm) a very intense green blue.

(*d*) The color change was a suggestion of green, quickly followed by a dark red brown, but when the straight acetic acid extract was used (without ether extraction) the color was a clear blue.

(*e*) The color change was a tinge of red in five minutes with the ether acetic acid extract (Schumm), but on using the straight acetic acid extract a clear red wine color quickly appeared.

(*f*) Color change was a green blue with the straight acetic acid extract (Schumm) and a clear deep green with the ether acetic acid extract (Schumm).

EXPERIMENT No. 2.

On the 8th, evening meal, — cold roast beef, the other meals, meat-free; on the 9th, evening meal, — beef pie, other meals meat-free; on the 10th, eggs, lobster, salt codfish and cream; on the 11th, eggs and asparagus (otherwise on 10th and 11th meals were meat-free). Stools passed on 8th, 9th and 10th not examined. Examination of stools on 11th, thirty-two hours after meal of meat pie, showed both the benzedin and Weber's tests negative. In the case of benzedin the feces solution was unboiled. The stool was then extracted by Schumm's method and both the benzedin and guaiac tests were found clearly positive. Stool passed on 12th, fifty hours after meat pie gave a negative guaiac by Schumm's and only a slightly positive benzedin. Although salt fish fiber gives a positive benzedin the experiment shows it does not cause a positive reaction after digestion.

I have applied the benzedin test (method of Schlesinger and Holst) to various substances with the following results: Raw green vegetables gave a slight positive reaction, though it was not found that they materially interfered with the test, in gastric contents or stools, and particularly in the latter. Raw wheaten flour, corn and oaten meal, potato, carrot, parsnip and squash, all gave a quick positive reaction; when cooked the result was negative with all. All meats, cooked and uncooked, gave a strong positive reaction. Raw fish, fresh, dry and pickled, and shell fish (oysters and clams) gave a positive reaction with benzedin; cooking much weakened the reaction, and the color change was chiefly confined to the tissue substance, the solution showing only a weak green. Cooked lobster, not mixed with the visceral portions, showed no benzedin reaction. After the ingestion of any form of fish the feces usually caused no benzedin reaction, sometimes slightly positive after fresh fish. Eggs, raw or cooked, did not give a positive benzedin. The presence of biliverdin in the urine or feces caused a very strong positive reaction, but bilirubin, hydrobilirubin (or urobilin) as found in the stomach contents, feces or urine, either gave no benzedin reaction at all or only a slight degree of color change.* Blaud's pills give a quick but not intense positive reaction with benzedin, but after ingestion of *Blaud's pills* (30 gr. daily), the feces gave no positive reaction with benzedin (by Schlesinger and Holst's method).

The requirements of any clinical blood-test are accuracy, delicacy and simplicity of application. All of the occult blood-tests embrace one or two of these requirements, but Teichmann's and the spectroscopic tests have already been considered as generally inferior to all others. Taking *guaiac* as a standard, the above comparative tests show the following:

The *aloin* test is accurate and was found about equal in delicacy to the guaiac test, by Weber's method; if, however, a slight distinct tinge of green or a red brown is taken to indicate blood, then guaiac will be found the more delicate test. At first one is likely to be impressed by the singleness of color change in the aloin test; but, on the other hand, the aloin is slow of action, particularly in the presence of small amounts of blood, and, furthermore, we do not have the choice between H_2O_2 and oil of turpentine, — it requires turpentine. The aloin test holds no distinct advantage over guaiac.

The *paraphenyldiamin* test (Störch-Boas test) was frequently found on comparison more delicate than Weber's, and is probably more delicate than any modification of the guaiac test, except possibly Schumm's. Still, the test is not so simple as the guaiac test, and the varying color changes are confusing, and, in examining stools, bile and other coloring matters, are as likely to interfere as in the guaiac test. Apart from its delicacy, I can find nothing to recommend the paraphenyldiamin over the ordinary guaiac test.

Benzedin is by far the most delicate of the occult blood tests. In fact, the objection has been repeatedly raised that it reacts to such minute quantities of blood as to be clinically useless. The modification of Schlesinger and Holst overcomes the objection of excessive delicacy of the test, and renders it more practical and exceedingly simple (it can be performed within two minutes) and also prevents any possible reaction from enzymes. But even this modification may not prevent small amounts of blood (even non-pathological) from giving a slightly positive benzedin sometimes, but practice soon teaches what degree of color change indicates occult blood.

Frequently the benzedin test is negative, and it is for this reason of great value, obviating the need of other tests, and this is particularly true as a test for feces.

A positive benzedin and a positive guaiac would be more trustworthy than a positive benzedin alone, and guaiac is a *safer* test than benzedin for stools where meat has *not* been excluded from the diet.

Benzedin and guaiac together meet every practical demand of a clinical test for the presence of blood.

I am much indebted to Dr. Pratt for important suggestions in the subject-matter of this paper, as well as for facilities offered in his clinic.

* I am much obliged to Dr. W. W. Barker, Medical House Officer, Massachusetts General Hospital, for a number of specimens supplied for these tests.

A CRITICAL ESTIMATE OF THE FERMENTATION SPECIFIC GRAVITY METHOD OF QUANTITATING SUGAR IN DIABETIC URINE.*

BY HENRY A. CHRISTIAN, M.D., BOSTON.

Assistant Professor of the Theory and Practice of Physic, Harvard University; Physician-in-Chief to the Carney Hospital.

In 1861 Roberts[1] described a method of quantitating the glucose present in diabetic urine, which he spoke of as " the clinical method," on account of its simplicity and ease of application. His method consisted in determining the decrease in specific gravity of the urine caused by the action of yeast. Yeast fermentation splits up the glucose present and its amount can be determined by multiplying the difference between the specific gravity of the urine before and after fermentation by 0.23. This gives the percentage of glucose present. Roberts compared the results obtained by this with those from other methods of that day for quantitating glucose, and showed the considerable accuracy of his method.

Of late years the method suggested by Roberts has been rather neglected. In its place titration with some form of copper sulphate solution, polari-

scopic estimation, a fermentation method which measures the amount of carbon dioxide formed in the destruction of glucose, or other methods have been very generally used and comparison of the results of these various methods have been published by a number of observers.

Of all methods the fermentation-specific gravity one appears to be the simplest for the general practitioner, because it requires no laboratory and needs only a bit of yeast from the kitchen and the urinometer or specific gravity bulb, which every physician has. How accurate is such a simple method?

The question of accuracy is to be answered by comparing the results of this method with those obtained with other methods. During the past two years I have been able, with the aid of picked students from the fourth-year class of the Harvard Medical School, working under my direction at the Massachusetts General Hospital, to make such a comparison. We have made daily quantitations of the sugar present in the urine of several diabetic cases by (1) the Fehling's copper sulphate titration method; (2) the polariscopic method; and (3) the fermentation-specific gravity method. The estimates have been made in part by myself, largely by the students under my supervision. It has been our attempt to apply each method with such care and attention to detail as might be expected of a careful clinician

working with adequate laboratory facilities. As a matter of fact, on the whole, more estimates of a given specimen were made and more attention was given to the avoidance of some of the commoner sources of error than it is fair to expect of even a very careful clinician. The polariscopic estimations were made with a Schmidt and Hensch half shadow saccharometer, and these results were controlled by a more accurate polariscope from the same makers.

The results of these estimations are graphically shown in Charts I to VIII. A glance at these shows a quite close agreement in the various quantitations. Chart III, which differs somewhat from the others, is from a case which during the first few days appeared to be excreting both levulose and glucose. At least this supposition would satisfactorily explain the considerable difference between the results of polariscopic estimation and those from the other methods. At the same time the urine on these days gave a strongly positive reaction with Seliwanoff's reagent, which reaction later disappeared. The occasional sudden variations seen in the other curves are probably due to errors in application of the method. All were typical cases of diabetes mellitus of moderate severity. In none was there coma or evidence of impending coma. The quantitations represent the per cent of glucose in a mixed specimen from the total 24-hour amount.

Chart IX shows the results of quantitating (*a*) normal urine to which glucose (Kahlbaum c. p.) has been added, and (*b*) 1% sodium chloride solution, in which glucose similarly was present. This shows a close analogy to the results obtained in diabetic urines.

To titrate a diabetic urine with Fehling's solution requires a considerable amount of time, care and laboratory equipment. The end reaction is not very sharp, and there is a considerable inherent error in the method. The polariscopic method requires an expensive instrument and the accuracy of the result is influenced by the presence of beta-oxybutyric acid, albumin, levulose and other possible constituents of diabetic urine.

The fermentation-specific gravity method as shown by the charts gives results as good as do the other methods. It is very simple in application, requires no laboratory equipment and involves a minimal cost for apparatus. All that is required is to take the specific gravity of the urine at room temperature, add a small bit of commercial yeast and place in a warm place, such as an incubator at 37° C., a heated room, near a stove or radiator, etc. Active fermentation soon begins and is evinced by bubbles and currents in the urine. When fermentation is finished the specimen partially clears and the evolution of gas ceases. A negative test with Fehling's or Nylander's solution proves the end of the process — 12 to 18 hours is usually sufficient. The specimen is now allowed to return to the room temperature of the previous specific gravity determination, and the specific gravity redetermined. The difference between these two readings, multiplied by 0.23, gives the percentage of fermentable substance expressed in terms of glucose.

A number of specimens were carefully filtered before the second specific gravity determination was made. This made no appreciable difference. The specific gravity bulb used was such as is sold to the physicians at a cost of from fifty to seventy-five cents. Many comparative readings were made, using a more accurately graduated longer specific gravity bulb and calculating the necessary allowance for temperature changes. Here again the differences are very slight, so slight that they might well be neglected. It is, however, important to use the same specific gravity bulb for both readings, since these cheap instruments vary considerably in their 1,000 level. Moreover, the specimen should be approximately at the same temperature at each reading, or a specimen with and without yeast be kept side by side and simultaneous specific gravity readings be made after the completion of the fermentation in the one, as first suggested by Roberts, for any considerable temperature variation will affect the specific gravity enough to change materially the result of the determination. Observing these few precautions, the results obtained are about as accurate as those given by the other two methods. The great simplicity of the fermentation-specific gravity method renders the chance of error in application slight, and it can be strongly recommended to the general practitioner in following the metabolism of cases of diabetes mellitus.

The facts presented above are not new. Yet it has seemed worth while again to call attention to so simple a method of quantitating glucose in urine, and to commend it as a sufficiently accurate method to enable the practitioner to treat scientifically his cases of diabetes mellitus. This is the motive of the paper. An accuracy sufficient for more exact chemical work is not claimed.

THE TREATMENT OF FEVER CASES IN THE PUBLIC SERVICE.*

BY C. A. DREW, M.D.
Medical Director, State Farm, Mass.

DURING the eighteen months ending April 1, 1907, 1,525 cases have been treated in the general hospital department of the State Farm. Of these 1,525 cases, 25 have been primary or secondary cases of lobar pneumonia. Of these 25 pneumonia cases, one died. All the others made good recoveries. Six cases of typhoid fever were treated during this period, all of whom made good recoveries.[1]

During the past three and one-half years, 38 cases of lobar pneumonia have been treated in this same hospital department of the State Farm with 3 deaths,— a mortality just below 8%. During this same period of three and one-half years, we have treated 30 cases of typhoid fever, all of whom made good recoveries.

* Read before the Massachusetts Association of City Physicians, Boston, April 2, 1907.

[1] Six additional cases of pneumonia, each are alcoholic, all of whom recovered, have been treated since April 1, 1907. No typhoid since April 1.

For six years prior to Oct. 1, 1903,— the beginning of our hospital year,— we had treated 63 cases of lobar pneumonia with 21 deaths, about the average mortality, we believe, among intemperate men, and our mortality from typhoid fever had been 3 in 18 cases,— about 16.6%.

Making due allowance for the difference in the type of typhoid fever and pneumonia in different years, and allowing also for a probable difference in the physical condition of patients, a difference in the degree of leucocytosis and a probable difference in the strength of the army of bacterial allies engaged in the assault, still the contrast is marked between a mortality of 33⅓% for pneumonia and 16.6% for typhoid fever in the six years prior to October, 1903, and a mortality of 8% for pneumonia in 38 cases, and no death in 30 consecutive cases of typhoid fever since Oct. 1, 1903. If we note the further fact that for the past eighteen months the mortality in lobar pneumonia has been but one in 25 cases, exactly 4%, then the contrast is even more striking.

We have chosen the statistics of the past nine and one-half years because the writer has been chief of the medical staff at the State Farm during this period. The same trained woman nurse has been in charge of the nursing department during the whole time. With the exception of a competent surgical dresser and male night supervising nurse, the whole nursing force has been made up from men prisoners, without orthodox training, serving time for drunkenness, selected because of a demonstrated kindly disposition and an aptness in caring for the sick. Changes have occurred each year in the personnel of the junior members of the medical staff, but my junior colleagues were just as watchful and just as faithful in carrying out every direction and just as competent in detecting early danger signals when the mortality was 33⅓% for pneumonia and 16.6% for typhoid fever as during the past eighteen months. We cannot say whether the early cases were more or less severe than for the past eighteen months. A systematic blood count, bacterial comparison and differentiation would have added much to the scientific value of our observation, but we are in about the position of the busy practitioner,— our whole medical force is pushed with clinical work and the more scientific laboratory details are often neglected. Basing an opinion on clinical symptoms, I would say that the types of cases have not differed greatly.

Of our last 25 cases of pneumonia, all except 2 had been hard drinkers for years; 4 of the 25 cases were over sixty years of age, and the one who died had cirrhosis of the liver as a complication. In former years our cases must have been nearly all chronic alcoholics, as, with very few exceptions, they were serving time for drunkenness.

We think we have learned something and have modified our treatment. Whether our modified treatment has really made the smaller death rate, only time and added experience may enable us to say. In so far, however, as our limited experience may justify, we feel that we have learned a better way. In the early days we were not inattentive nor nihilistic regarding treatment. We followed the masters in medicine and believed that an abundance of fresh air, attention to the bowels, the most nutritious and easily digested diet, and liberal use of strichnine, digitalis and whiskey to meet heart weakness were our most effective weapons. We held it good reasoning that a man whose nervous system had been accustomed to large quantities of whiskey would be in great danger if he were not given alcoholics in liberal measure when down with typhoid fever or pneumonia. Our nurses were directed to give all the water the patient wanted, but the emphasis was on the whiskey and strychnine, and the water was credited principally as a convenient agent for diluting the alcoholic. In the light of our added experience, we are inclined to believe that the water added to dilute the whiskey was the more helpful part. We knew, of course, that water constituted 70% of the body weight, and of the brain even a larger percentage than the average for the whole body. We knew, when we stopped to think, that water was an important ingredient of the solid organs only in less proportion than in the digestive juices, lymph and blood. We knew how every muscle would shrink, stiffen and weaken under moderate heat by the rapid evaporation of the ingredient water upon which its flexibility largely depends. We knew the dependence of kidneys, lungs and skin and every excreting organ upon the maintenance of the normal fluidity of the vital secretions. Of all these facts we had a theoretical knowledge, and yet we did not fully know, because we did not allow the admitted facts a central place in the field of our consciousness. We did not realize how much the vital functions would be depressed by the too rapid loss of that life-sustaining oxide of hydrogen, known to the medical students as H_2O. If we had fully considered pure water in relation to that mixture of oxygen upon which our life so directly depends, and had remembered that the proportion of oxygen is even less in the air we breathe than in the water we may drink, — then we might not have been surprised to have found the vital forces rallying when reinforced by hot water and sodium chloride, in the proportion of the so-called normal salt solution, even more than when reinforced by the direct inhalation of oxygen or when stimulated by strychnine and alcohol. We do not suppose that water gives up its oxygen as does the air, and we do not suppose the hydrogen of water plays so large a part in the phenomena of life as the active nitrogen molecules in the atmosphere about us, and yet experience seems to suggest that a large quantity of pure water is only second in importance to an abundant supply of pure air when a high temperature and excessive exhalation of water is rapidly shrinking the muscles, and bacterial toxines are testing the eliminating powers of skin and kidneys beyond their normal functional capacity.

We knew, of course, in a general way, the tonic effect of cold and the atonic effect of heat upon all the ganglia of the sympathetic system, as well as upon the great cerebrospinal nerve centers them-

selves. We had been taught of the vaso-motor controlling centers in the medulla and of subordinate vasomotor centers located at different levels in the spinal cord. We had learned that there were vaso-constrictor and vaso-dilator fibers from these ganglia supplying every artery, and not these alone but even, as it is alleged, supplying lymph-vessels and veins. These facts of physiology had a place in our memory, but were crowded from the center of the field of consciousness. The masters in medicine had not laid emphasis upon these physiologic facts and we did not appreciate the therapeutic possibilities to be reached by the multitude of nerve terminals within the fifteen or twenty square feet of skin covering the human body, which may be played upon mechanically and stimulated by heat and cold to re-enforce exhausted ganglia and heart muscles, to accelerate or slow the blood current, to deepen respiration and regulate temperature and even to change the composition of the blood itself, — to which facts Winternitz in Germany, Rovighi in Italy, and Thayer, of Johns Hopkins, and others had testified. The evidence was experimental and seemingly conclusive, but these were not our masters in medicine, and their teachings were little regarded. It remained for Baruch, of New York, and Kellogg, of Michigan, to rouse our interest in the possibilities of hydrotherapeutics to a level at which it could bear fruit. These were they who gave definite instructions to which the value of teaching so much depends.

Baruch's statement, that he had not lost a case of uncomplicated croupous pneumonia in private practice since the adoption of the management of patients outlined in his work on hydrotherapy, would be more forceful if he would give the number of cases treated; but in a lecture delivered to a medical class in Los Angeles some six years later (February, 1904) this teacher repeats essentially the same directions as found in his textbook and adds: " In my hospital service the mortality has been reduced 50%, as shown by 156 cases collected by Dr. Albert Wittson, of New York. The mortality under this newer management has been 12%. Considering the desperate character of the cases brought to the hospital in its ambulances, and the fact that they are sometimes almost *in articulo mortis*, this is not a bad record. . . . In a fairly extensive private practice I may say with some hesitation, but with entire sincerity, that during the past ten years I have been under the necessity of reporting only one death from primary croupous pneumonia to the Board of Health. The number of cases I cannot state, but I am willing to accept the verdict of the New York Board of Health."

We can accept Dr. Baruch's statement at its face value, for we know he has had a large experience, and we believe he is not a physician who " plays to the galleries." The evidence seems to justify the claims of the leaders in hydrotherapy that cold applications to the skin with friction, or the reactions following such application increases hemoglobin and the number of red corpuscles in the blood current and the white blood corpuscles even to a much greater extent. It seems to be proven that hemoglobin may be increased 10% or more, the red blood cells 25% or more, and the white cells, or leucocytes, may be more than doubled by these hydriatric measures.* It seems also that a high temperature has the opposite effect on red and white cells in the blood current. The fact that this marked increase after short cold applications lasts but a few hours, unless the application is repeated, and that it is usually accompanied by a decrease in the size of the spleen lends support to the hypothesis of Winternitz that the red and white corpuscles are released from being pent up in spleen, liver and other vascular organs by stasis of the blood current whereby the red cells are enabled to resume their important function of delivering oxygen and the white cells are again free to battle for the human organism against the bacterial allies, which latter, to borrow from Bunyan and Osler, serve under the banner of " The Captain of the Men of Death."

Such are some of the considerations which lend strength to our faith that we have learned a better way to treat patients down with acute self-limited febrile diseases. Toxemia is the enemy we have most to fear. Our strongest allies are skin, kidneys and white and red blood corpuscles. To expel, so far as possible, the poison in the bowel is our first move in defense. To support our allies with an abundant supply of pure air and pure water all through the fight is of the greatest importance. We believe the amount of water required by the body in health is no fit guide to the amount required when the heat of fever is multiplying the water exhaled and evaporated. To quiet the pain and sustain the heart in penumonia, we apply cold, wet compresses, wrung so they will not drip, and covered with a dry flannel or Turkish towel over the whole chest or over the affected side and changed every hour, or else use the specially designed pneumonia ice-bag, with drainage, planned by Dr. P. A. Aurness, of Minneapolis. This pneumonia ice-bag is a powerful cooling agent and is so constructed that it fits either side equally well. Because of the drainage tube, the melting ice is much more refrigerant than an ordinary rubber bag containing ice water. This may be applied outside of a night-robe or gauze undervest. No patient has complained of discomfort because of this ice-bag, and no patient has failed to receive apparent benefit from its use. I would choose to use the less powerful cold compress in children, and I would take care that this ice-bag was not kept on after beginning resolution in pneumonia, nor from midnight till sunrise after the fourth day when beginning resolution with a rapidly falling temperature may be expected. Dr. P. A. Aurness, of Minneapolis, whose name this pneumonia ice-bag bears, reports more than 100 cases, including five cases of double lobar pneumonia, with no death and without complications to retard recovery. Dr. Aurness uses liberal doses of some mild alkaline mineral water and creosote carbonate every four hours in from five to fifteen

* Rational Hydrotherapy, Kellogg, p. 120.

drop doses besides saline laxatives and saline enemas; also stimulants of brandy, strychnine and digitalis when indicated. By saline enemas, Dr. Aurness may mean enemas of "normal salt solution," which we have found very useful, given warm, when the heart has shown a danger signal.

While Dr. Baruch's plan of cold compresses, frequently changed, has some theoretical advantages, our experience with the Aurness pneumonia bag has been so fortunate and the dry cold so convenient to apply outside of a night-robe or thin under flannel that we doubt if cold water compresses would do better for our adult cases. We are inclined to think the cold compresses, wrung out and applied every hour, as directed by Baruch, are more quieting to the irritated nerve centers, because the cold is quickly changed by the heat of the body to a neutral or warm compress, while the gentle shock, repeated hourly, sustains nerve tone and keeps up tonic capillary dilatation.

If we had a trained nurse with every case, at all hours, we would more often choose the wet compress for theoretical reasons. When the temperature is low and the nervous symptoms very prominent, we would follow Baruch in every detail. When the fever is high, the pain in the side marked, and the nervous symptoms not so prominent, the Aurness ice-bag, in our hands, has been very satisfactory.

If we had small open wards of about six beds each, so that we could reserve one ward for pneumonia and another for typhoid fever and had graduate professional nurses to care for all these infectious cases, then we would count ourselves fortunate indeed. The best we can do under our present crowded condition is to care for each infectious case in a single room, with a capacity of about one thousand cubic feet. Our "natural nurses," with the most humane intentions, are very apt to close the window when the doctor has gone, lest the patient take cold. But in spite of these disadvantages, we think it not too much to hope that we may continue to keep the mortality in croupous pneumonia and typhoid fever below 10%. In indulging this hope we do not forget the statement of Strumpell,* endorsed by other teachers, that "every case of drunkard's pneumonia is to be regarded as very unfavorable."

In conclusion, we have not changed our early opinion that there is no specific for typhoid or pneumonia that can be depended upon, although we are willing to accept an antitoxine when proved and found true. We do not use venesection, tartar emetic, veratrum, aconite, poultices, blisters or wet cups; nor mercurials, except an initial dose of calomel, which may be or may not be better than a saline purge. We have not tested bryonia, phosphorus aconite or arsenic of the homeopathic pharmacopeia, and are not prepared to deny to these drugs a specific action. We do give an occasional small dose of morphine, codein or one of the coal tar products, but, personally, I always feel in the presence of this necessity that our natural weapons of defense have not been well used.

* Text Book of Medicine, p. 186.

In typhoid fever we have used acetozone † quite extensively and have credited it with germicidal and antiseptic properties. We have given this as an intestinal antiseptic, potent, if potent at all, by virtue of the nascent oxygen it gives off when decomposed. Of this antiseptic, we give an ounce of a one-tenth of 1% solution every hour, followed by six or seven ounces of pure cold water, if the patient will readily take that much. Typhoid fever patients rarely object to this solution and commonly take a glass of pure water readily to take away the taste. This we consider an additional advantage. We have repeatedly seen the temperature rise and abdominal discomfort increase when acetozone was omitted and promptly decline when it was resumed. This experience has led to the conclusion that in this organic peroxide known as "acetozone" we have an entirely harmless drug of real value.

It has been held by some that the practical result of giving fever patients liberal hourly draughts of cold water is to rob the blood of its normal salts, coincident with the more active elimination of the toxines of living and dead bacteria. We respect this opinion because it seems to be based on a physiological principle, and we meet the objection by adding the most important salts of the blood to the diet or give them in the form of a mildly effervescing drink. In pneumonia we often add 2½ gr. of sodium chloride, 1 gr. of pot. bicarbonate, and 1 gr. of ammonium carbonate to 4 oz. of cold water, to which solution we add a teaspoonful of lemon juice and give every hour while the mixture is slightly effervescent. By following this with 4 oz. of pure cold water, we think we refresh the patient, assist the skin and kidneys in their eliminating function, keep up blood pressure and sustain the heart. We rarely see the necessity of giving strychnine or an alcoholic till the onset of resolution in pneumonia, and more rarely still do we give an alcoholic in typhoid fever at all. This is about the sum total of our internal medication. The pure cold water we give, and the pure air we try to allow, we count first, and esteem the drugs we give of secondary importance. For nourishment, other than pure water, we depend largely upon milk, which is substituted for cold water once in three hours. If for any reason we use peptonized milk, which we assume is more quickly digested, we substitute the milk every second hour.

It is easy to understand the passive relaxation of the arterioles and capillaries of the skin under a hot poultice, and easy to understand how the load on the heart proper is lightened by the ensuing dilatation of the vessels of the skin. It is easy to understand the temporary relief of dyspnea in pneumonia from hot applications, but not so easy to understand why an ice-bag, a cold, wet pack or cold compress over the lung should ease the load on the heart. Clinical experience demonstrates beyond a peradventure that this is a fact, but the physiological law explanatory of the fact is not so commonly understood. Aur-

† See Note 1 at close of article.

ness testifies that an ice-bag properly made, with drainage, produces "such a vasomotor dilatation, evidenced by an intense hyperemia, as no other means known to science can produce without injury to the parts covered." Baruch quotes from and endorses Woods Hutchinson to the effect that the whole arterial system participates in the rhythmic muscular action of the heart, of which it is a less specialized extension. He accepts the term "skin heart" as used by Hutchinson and holds that cold applications stimulate the vasodilators and increase the force of the rhythmic contraction of arterioles. This increased tonicity of the "skin heart," according to this theory, so greatly increases its propulsive power that the slow blood current in the skin is augmented to the relief of the central heart, and the more rapid elimination of waste and toxines.

It seems likely that the majority of the members of this society may not accept the theory of a "peripheral" or "skin heart." Baruch and Kellogg give a list of the men upon whose experimental work their faith is based. I would especially recommend the careful reading of Baruch's work because it is not only well written but is comparatively brief.

If our experience were your experience, I would think the reading of this paper hardly worth while. In response to the kind invitation of Dr. Gleason to lunch with you and talk to you I read you of those things which have proved helpful to us. We are not wedded to any theory or system of medicine. If the future shall reveal a specific against the Ebert bacillus or the Sternberg-Fraenkel diplococcus, we will welcome it gladly. In the light of our present experience, we hold we can best assist Nature by supplying liberally Nature's own life-sustaining remedies. As an east wind is to the heat-stricken children of the poor in Boston at the end of a torrid week in August, so pure cold water in liberal measure internally and intelligently applied externally * is to the fever-stricken children of the poor at all seasons.

Note 1. Acetozone is a mixture of equal parts of benzoylacetyl peroxide and an inert absorbent powder with a chemical formula of $C_9H_8O_4$. In the presence of water it undergoes hydrolysis and slowly decomposes. Such hydrolysis is said to be necessary to develop its full germicidal activity. This drug is one of the "organic peroxides" in which an excess of oxygen has been combined in such a way that it is somewhat slowly given off in a nascent condition. It is soluble in water at 77° F. in proportion of 1 to 1560.

Note 2. To obtain the best results, cold water given internally to fever patients should be at about 40° F. Cold compresses for adults should be dipped in water as near 60° F. as possible. For children under five, compresses at 80° are better. For children a full bath at 10° below the temperature of the body, with friction prolonged for twenty minutes, is very helpful. This general principle should be observed: the colder the water the shorter must be the application. Water is a potent remedy and may do harm if applied when the body is not in fit condition to react promptly to cold applications. That cold wet or cold dry applications should not be applied when the skin is cold or moist with perspiration goes without saying. When the skin is cold and clammy, the call is urgent for hot, dry flannels.

* See Note 2.

ARTERIO-VENOUS ANASTOMOSIS.†

BY JOSHUA C. HUBBARD, M.D., BOSTON.
Assisting Visiting Surgeon, Boston City Hospital; Assistant in Surgery, Harvard Medical School.

My experience in arterial surgery has been obtained in two cases by doing an arterial venous anastomosis for reversal of the circulation. I feel that I have learned from them, although the number is small, certain facts which are worth recording. To make clear these points I will report the essential details of each case.

The first, already published in the *Annals of Surgery* for October, 1906, was that of a man of eighty years with senile gangrene of a portion of the right foot. Physical examination showed him to be a decidedly senile old man, with atheromatous arteries and a systolic heart murmur. No pulsation could be felt in the right dorsalis pedis artery. In May, 1906, he was operated upon. The femoral artery, which was decidedly atheromatous, and vein were isolated in Scarpa's triangle below the origin of the profunda and divided between Crille's clamps or elastic ligatures. The upper end of the artery was then invaginated into the lower end of the vein and the distal end of the artery into the proximal end of the vein. A complete reversal of the circulation was thus established. The technique of the invagination was as follows: Three double headed sutures were passed equally distant through the entire wall of the artery from inside out. The needles were then passed into the lumen of the vein about a quarter of an inch and at this point through its wall. When these sutures were drawn tight the artery was pulled into the vein. Re-enforcing sutures, including only the outer portion of the arterial wall, were placed here and there to catch the edge of the overlying vein to the artery. Number 1 Pagenstecher thread was used for all these sutures. When the controlling clamps were removed there was no leaking at either suture line and weak pulsations in the vein could be felt for a short distance below the anastomosis. There was absolutely no shock shown by the patient and recovery from the operation was satisfactory in spite of the fact that the senile condition of the patient made it difficult to keep him in bed or a dressing on the wound. After the operation the appearance of the leg did not change. There was no edema, dilatation of the veins or cyanosis. The gangrene which existed before the operation spread a little and then a line of demarkation formed. When the foot was later amputated, at the point of election on the tibia, both tibial arteries contained arterial blood. The stump healed satisfactorily but slowly. In March of this year, ten months after the operation, I saw the patient. He had a stump that was well supplied with circulation. There was no difference in appearance or size of this leg and the unoperated one.

Clinically this case was most successful, but the exact meaning of the presence of arterial

† Remarks made before the Academy of Surgery, Philadelphia, May 10, 1907.

blood in the tibial arteries at the time of the amputation I do not know. It seems that the arterio venous anastomosis must have increased in some way the amount of blood in the leg, for it is hard to believe that an amount of blood so small as to permit gangrene of the foot would be sufficient to nourish for ten months an amputation stump only a slight distance above the gangrenous area; and had clots formed at the sites of the anastomoses, it seems most probable that the gangrene would have extended rapidly up the leg instead of remaining localized.

The second case was that of an old woman of sixty years, with senile gangrene of the foot and a portion of the leg. The arteries were atheromatous. She was operated upon during February of this year. The femoral artery and vein were isolated in Scarpa's triangle and divided between clamps or ligatures below the origin of the profunda. The artery was much calcified and was so hard that some force was necessary to drive the needles through it and so brittle that the stitches tore out most easily. The intima formed a distinct lining to the vessel and was much like a second smaller tube inside a larger one. These characteristics of the wall complicated the technique immensely as I attempted to make my anastomosis according to Carrel's method, turning the walls so that at the suture line intima should come in contact with intima. The artery was so much like a pipe-stem that this was impossible, although a conscientious attempt was made. The ends of the artery and vein were therefore cut off freshly and the artery invaginated into the vein, as in the first case, the only difference being in the use of vaseline in this case to smear the ends of the vessels. The distal end of the artery and the proximal end of the vein were then ligated. The vein pulsated after the controlling clamps were removed. Pagenstecher No. 1 was used. There was no shock and no change in the appearance in the leg. Ten days later it was necessary to amputate above the knee for the gangrene which had been present before the operation. During these ten days it had become more pronounced, but its limits had extended only a little. During the amputation the anastomosis was cut down upon and removed. The artery was found filled with a loose, easily detached clot. This case was, therefore, a distinct failure.

From these cases I believe it is perfectly evident that there is no danger in continuing our investigations further, as there is no shock following the operation. Carrel's method is not applicable to a certain number of the cases where the operation is done on old persons with atheromatous arteries. In young persons and on experimental arteries it doubtless is most satisfactory, but as the operation has been proposed to cure conditions dependent upon lack of circulation in the extremities some other technique must be found, as practically all cases, except perhaps some due to trauma, will necessarily be in elderly persons. An objection which may be raised to the invagination method as employed in the above cases is the fact that the divided end of the artery leaves a certain portion of its wall in the blood stream uncovered by intima, which favors clot formation. This method was introduced by Dr. Murphy * in 1897 for the repair of the continuity of an artery and was recommended only after experimentation. The slight modification of invaginating the artery into a vein instead of into another portion of the same artery would seem to me not to invalidate the method. However, as at present, this objection might be raised, I am working on some scheme to obviate this difficulty, but as yet unfortunately cannot report results. Two ways to avoid this have occurred to me. One is by smearing vaseline or some other substance onto the cut end of the invaginated artery to keep it out of the blood stream. The other way was suggested to me by the appearance of the arterial wall in the second case, where the intima formed a distinct layer inside the others and one which remained intact when the others cracked away from it. I have thought that it might be possible to cut the outer layers of the artery a quarter of an inch or so back of the intima and thus leave a greater length of initima as a cuff, the back of which could be covered with vaseline, so that when invaginated into the vein it might stick to the venous wall and cover over the cut end of the outer portion of the artery.

Clinical Department.

GLOTTIC SPASM OF NASAL ORIGIN IN ADULTS.

BY FRANK A. CONLON, M.D., LAWRENCE, MASS.
Former Hospitant in the Koschier Clinic, Vienna.

SPASM of the glottis of nasal origin in adults, a rare form of reflex laryngeal neuroses, was first described by Hack in 1882, and since that time fourteen cases have been published, making in all but fifteen recorded cases. To these I propose to add the sixteenth, but before doing so shall attempt to give a short résumé of the cases so far reported.

CASE I. Hack.[1] A healthy physician, whose disposition was not at all nervous, suffered at night severe attacks of dysponea, caused by glottic spasm. Examination of posterior nares disclosed a marked congestion of the mucous membrane. After painting the posterior nares with silver nitrate, attacks disappeared for a long time, only to reoccur with the advent of a mild angina. Posterior nares again painted and attacks have not since reoccurred.

CASE II. Heryng reports two cases. Man,[2] forty-nine years old, who had been suffering from spasm of the glottis for three years, the attacks occurring during day and night. Examination of the larynx showed nothing abnormal. Posterior nares and pharynx normal. Anterior rhinoscopy showed polyp in left nares in region of middle turbinate. Polyp was removed and patient was entirely free from symptoms for a year. He then returned, suffering fresh attacks, and on examining the nose a new polyp was found.

This polyp was removed and attacks ceased, and have not since reoccurred.

Case III. Woman,[5] eighteen years old, who had been subject to spasm of the glottis for the past two years. She also gave a history of practising masturbation for two years. Besides spasm of the glottis, she had spasm of the bronchiols. These attacks were so severe that tracheotomy was resorted to, and the canular worn for two months, when it was removed. She soon returned, however, suffering a renewal of attacks, and tracheotomy was again done. Nasal examination was now made for the first time. Larynx and pharynx found normal. On examination of the anterior nares she was found to have a deviation of the septum, hypertrophy of the anterior end of the lower turbinate, right side, and a marked swelling and redness of anterior end of the lower turbinate on left side. Treatment consisted of touching up both turbinates with chromic acid, and during this treatment the canular was removed. Result, patient cured of both glottic and bronchiol spasms.

Case IV. Przedbreski's [3] case was a young woman, eighteen years old, who presented numerous symptoms of hysteria, with anesthesia of the epiglottis. Her attacks occurred most frequently in the evening, and were preceded by symptoms of intense nasal irritation. Larynx and pharynx normal. Septum deviated to the left and marked hypertrophy of the lower turbinate. Her hysterical condition was treated for three or four months without improvement, when the lower turbinate was then cauterized with chromic acid, after which attacks of spasm of the glottis entirely disappeared.

Case V. Soudrille's [4] patient was a brother physician, forty-four years old, who had suffered five or six attacks of spasm of the glottis during the previous fifteen days. During these attacks the face was congested and the hands blue. These attacks occurred at no special time, and without any prodromal symptoms. The examination of larynx and pharynx was negative, but examination of nose showed hypertrophy of the two middle turbinates and a swelling of both lower turbinates. Polyp was also found. Treatment consisted of removal of the polyp and irrigation of the nose with administration of potassium bromide. Result, patient cured.

Case VI. Ruault [6] reports the following five cases: 1. The first case was a woman, twenty-five years old, who had been suffering from these attacks for some twenty-nine months. Her first attack came on soon after her marriage. These attacks reoccurred every six to eight days, and always came on at one or two o'clock in the morning, while the patient was asleep. Her husband remarked that just previous to an attack his wife's breathing was markedly changed. This woman had always been extremely nervous, but presented no real symptoms of hysteria. Larynx normal and pharynx presented the appearance of a chronic catarrh. On examination of the anterior nares the introduction of a speculum was found to be extremely painful. Marked deviation of the septum and swelling of the two lower turbinates and middle turbinate on the right were found. After treatment, consisting of applications of chromic acid to turbinates, patient reported that she was free from all attacks of spasm of the glottis.

Case VII. 2. A woman forty-three years old has been subject to attacks for the past twenty-years. Her attacks date from the time of her marriage and occur sometimes at night and other times during the day, she having been taken with an attack in the middle of the street. At the time of her examination she presented a slight laryngeal catarrh and hypertrophic rhinitis. Treatment consisted in applications of the cautery to the anterior ends of lower and middle turbinates. Result, patient entirely cured.

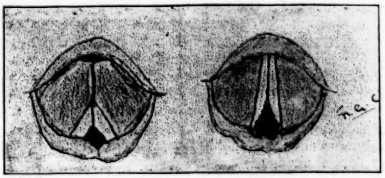
Case VIII. 3. A woman, twenty-seven years old, subject to spasm of the glottis for the last six months, first one occurring on going in bathing in the ocean. Her attacks occurred more frequently at night, but occasionally during the day. Larynx normal and marked swelling of anterior ends of lower turbinate. Patient treated with irrigations of tepid water with borax and sodium bicarbonate. Result, patient cured.

Case IX. 4. Woman, thirty-eight years old, had been suffering from spasm of the glottis for one month, first attack occurring after severe cold. These attacks occurred both during day and night, and were preceded by short dry cough. Woman cried at the least provocation, and presented other hysterical manifestations. Menstruations have always been more or less painful, and physical examination showed marked tenderness in region of the right ovary, and signs of incipient tuberculosis in right lung. Examination of larynx and pharynx showed nothing abnormal. Examination of the nose showed septum deviated to the right, and left lower turbinate swollen and red. Introduction of speculum was extremely painful. Treatment consisted of irrigations of tepid water and borax. Result, patient cured.

Case X. 5. Man, fifty-one years old, had been suffering from attacks of spasm of the glottis for three weeks, time of attacks not given. Patient said that attacks were brought on by secretion dropping in throat. Examination of the larynx showed a slight hyperemia. Patient also presented evidence of nasopharyngeal catarrh. Examination of the nose showed septum deviated to the right, hypertrophy of the right lower turbinate, and a marked swelling of the left lower turbinate. Patient treated by irrigations of tepid water and borax used twice a day. Result, cured.

Case XI. Bosworth [22] reports two cases: 1. Man who had suffered for thirty-three years with spasm of the glottis. His first attack closely followed diphtheria. These attacks always occurred at night. Examination of the nose showed marked hypertrophic rhinitis and deviated septum. Treatment consisted in removal of the deviation and cauterization of the turbinates. Result, patient greatly relieved.

Case XII. 2. Woman, fifty years old, whose attacks always came during sleep, was found to have numerous nasal polypi, after the removal of which she never experienced another attack of glottic spasm. Bosworth also reports two cases of glottic spasm, the cause of which he gives as atrophic rhinitis. In both these cases the attacks occurred only at night. After treatment by nasal irrigation patients were entirely free from glottic spasm.



Case XIII. Hamilton Stillson [17] reports a case of a man, printer, thirty years old, who said he found himself every night in the middle of the floor gasping for breath; attempts at inhalation very noisy, very difficult and distressing. Could not state length of spasms, seemed several minutes. Stated that he could not catch his breath until unconciousness had almost supervened. These attacks never occurred in day time, but only at night and during sleep. Under good illumination Stillson elicited an exhibition of the spasm by touching the vocal cords with a probe. "Cords fell together like a valve, and efforts at inhalation seemed to suck them together." Short gurgling whoop was heard, which was repeated about once a second. Between the whoops there was a period of exhalation, short and easy. Profound cyanosis supervened, the ocular conjunctivar being markedly congested. Patient's distress was so marked that chloroform was administered, whereupon the inhalation became deeper

and less noisy. Attack lasted about thirty seconds. Pulse slightly irregular and slightly accelerated. Patient never used alcohol, tea or coffee, and presented no evidence of rheumatism, syphilis or tuberculosis. Examination of nose and throat revealed a large spur on left side of the septum and a deviation toward the left. There was a hypertrophy of the lower middle turbinates, right and left, polypoidal degeneration of the mucous membrane, hypertrophy of the lingual tonsil and hyperemia of the epiglottis and false cords. With cocaine anesthesia hypertrophy of the lower turbinate and spur were removed. Result, complete cure.

AUTHOR'S CASE. Mrs. K., forty-three years old, came to my office with the following history: She had always been a healthy woman up to the time when she came to this country, seven years ago. At that time she suffered severe pain with swelling in the region of the appendix. Physician consulted then advised operation. She did not, however, submit to the operation, and continued to suffer pain off and on until a year ago. She has had two children, and no miscarriages. She consulted me in regard to attacks of suffocation, which occurred four or five times a day. She said that these attacks appeared without any warning or cause, and were so severe that she and her family thought at times that she would surely die. The first of these attacks occurred two years ago, and during the following year she experienced on an average one or two attacks a month. During past year they gradually increased in frequency. A little over a month ago she suffered from a severe cold in her head, and since that time has had from two to five attacks a day. They came on at no especial time, occurring occasionally during the day, and other times at night, although previously her attacks always came on during sleep. She has never been a nervous woman, and except for the pain in her right side and this present trouble she has been very healthy.

Patient was very hoarse and it seemed quite an effort for her to speak. She said that in the morning her voice was clear, but that it gradually became hoarse and "clogged up" toward evening. Examination of larynx showed typical picture of acute catarrh. Pharynx and nasal pharynx were normal. Anterior rhinoscopy showed marked deviation of septum to right, small spur and marked hypertrophy of middle turbinate on the left. With the application of a 1% solution of silver nitrate to the larynx I was able to elicit a spasm of the glottis which her husband and son said was typical of one of her attacks. Patient's face drawn as if in great pain. During the inhalation her head was thrown back and a short, loud whoop was heard. On expiration, head bent slightly forward, and expiration accomplished with apparently no effort. There was an interval of one second between inspirations. The duration of the expiratory action was about twice the length of the inspiratory. An examination of the larynx now showed almost complete closure by apposition of the true vocal cords up to the posterior vocal processes, and also an apposition of the false cords for slightly more than half their length. During expiration there was a slight relaxation of the true cord and a rather marked deviation of the false cords. Patient was now becoming cyanotic. After dashing cold water in her face three or four times the spasm relaxed. The duration of this spasm was one minute and a half, which her husband said was about one fourth the usual length of an attack.

Operation advised, and patient requested to report in four days. She returned, however, on the second day, and begged me to operate, as during the previous twenty-four hours she had suffered six spasms. After applying a 1% solution of cocaine the anterior end of the middle turbinate was removed with a cold snare. Nose then firmly packed with sterile gauze and patient returned the following day and said that she had one slight attack the previous night. Gauze removed and patient had considerable bleeding, which was checked by application of tannic acid. I intended operating on the spur and septum, but as the patient was entirely cured by the operation on the turbinate, she would not consent to the second operation.

Glottis during inspiration. Glottis during expiration.

Spasm of the glottis, as it occurs in these cases, is a spasm affecting all the adductor muscles of the larynx with the exception of the arytenoideus. It is a partial spasm, in contradistinction to that occurring in laryngeal vertigo, which is a complete glottic [16] spasm.

Diagnosis. — In making a diagnosis of glottic spasm of nasal origin, the following conditions which may give rise to spasm of the glottis in adults must be excluded: Intra-laryngeal; foreign bodies, tubercular and syphilitic affections, irritating vapors, polypi, edema and infiltrations. Extra-laryngeal; tabes, epilepsy, hysteria, tetanus, hydrophobia, chorea and tetany.[15] Hypertrophied tonsil, aneurysm of the left common [10] carotid or of the aorta,[11] dilated [12] stomach,[13] cervical adenitis,[19] goiter,[9] or pressure on phrenic [7] nerves [8] may also give rise to spasm of the glottis.

Dysponia spastica. — Spasm of the glottis only on attempted phonation is called dysponia spastica. The glottis remains closed as long as patient attempts to use his voice, and opens when there is no further attempt at conversation.

Laryngeal vertigo. — Patient is seized with giddiness, blurring of vision, and unconsciousness, caused by a complete glottic spasm, remaining in that condition but a few seconds, during which there may be spasmodic twitchings of the limbs and face.

The cause and origin of reflex. — The sensory nerves of the nose are supplied by the trifacial. The anterior ethmoidal nerve, a branch of the nasal nerve, supplies the anterior portion of the interior of the nose, while the remaining portion of the nasal cavity is supplied by the posterior nasal and by a branch of the dental. The reflex travels toward the center along the trigeminus, toward the periphery in the vagus. This has been demonstrated experimentally on animals by Francis Franck.[18] The results obtained showed the cause of this reflex in 11 cases to be congestion or hypertrophied turbinates, in 2 cases polypi, in 2 cases atrophic rhinitis, and in 1 case chronic

nasal catarrh. That the exciting cause of the reflex is the periodic apposition of mucous membrane might be applicable in some of the cases, but is not in all. I believe the impulse arises in the termination of the sensory nerve, from a congestion or irritation of the surrounding tissue.

Hysteria. — That a nervous or hysterical disposition predisposes one to these attacks is not at all evident from an examination of these cases. In but 3 cases has any mention been made of this disposition on the part of the patient, while most authors have been particular to emphasize the fact that aside from glottic spasm their patients were in especially good health.

Sex. — Of the cases here collected, 57% were females and 43% males. This affection is much more equally divided as to sex than one would be led to infer from the perusal of the present textbooks.

Age. — In males the average age was forty-three years, in females, thirty-two.

Time of attacks. — In 7 of these cases the attacks occurred only at night, and in 2 others occurred most frequently at night, but in the remaining 7 cases the attacks came on at no especial time, which seems to contradict the statements made in regard to these attacks in our textbooks on the subject, which state that the attacks occur only at night. In my own case, during the first year in which she was subject to spasm of the glottis the patient experienced the seizures most often at night, but with the increased frequency of attacks they occurred as often during the day as during the night.

Sexual apparatus. — In 6 of the cases here collected we find direct connection with the sexual life or apparatus; menopause, 2; diseases of the sexual organs, 1; masturbation, 1; occurring directly after marriage, 2. Chaimberlain [14] reported 2 cases occurring in women at time of menopause, but in both cases neglected to examine the nose for nasal lesions. Przedbreski's [20] case of spasm of the abductors is of interest in that the attacks were most frequent at menstrual periods, and much more severe when patient went over the usual time.[21] Störk reports an interesting case in this connection. An impotent man married, and soon after both husband and wife suffered from spasm of the glottis. At this time the woman received treatment, but her condition failed to improve. She was seen later completely cured and the mother of three children, and as Stork explains: "*Sie hatte sich anderweitig Hilfegesucht und gefunden.*"

Reports of Societies.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Twenty-first Annual Meeting.
Held at Washington, D. C., May 7 to 9, 1907.

Dr. Harvey G. Mudd, of St. Louis, Vice-President, in the chair.

Tuesday, May 7, First Day.

THE PESENT STATUS, TWO YEARS AFTER THE ORIGINAL REPORT, OF EIGHTEEN MALE CASES OF ROENTGEN RAY STERILITY.

This report, by Dr. F. Tilden Brown and Dr. A. T. Osgood, of New York, was read by Dr. Osgood. In their original report it was stated that repeated long exposures to the Roentgen rays produced sterility in the male. They were still of the same opinion. Some had escaped permanent injury, doubtless because of avoidance of exposure. Some who then had bad records were now the fathers of children. The condition was not permanent in all cases. Some in whom no spermatozoa could be found and who were thought to be permanently injured had improved considerably, but the majority were still in the same condition. All who had done extensiv ex-ray work for several years showed an absence of spermatozoa. The amount of injury was directly proportionate to the changes in the spermatogenetic cells. The condition could be produced in animals, but required considerable exposure. The spermatozoa themselves were found to be highly resistent to x-ray exposures. There was no relation between the effect on the skin and that on the deeper organs. In no case had there been any evidence of deterioration of sexual activity.

Dr. Edward L. Keyes, Jr., of New York, asked Dr. Osgood whether he considered the improvement in some cases due to precautions taken by those men who improved which were not taken by some who did not improve, or whether he had seen improvement occur in men who continued to use the x-ray without precautions. He thought it might be interesting in this connection to detail a report made by Dr. Lapowski, of New York. He had reported that he had a case of eczema of the anus which resisted the ordinary methods of treatment. He sent the patient to be x-rayed, with a knowledge of the danger of producing sterility by the x-rays, and especially specified that the patient's testicles should be protected by a lead screen. The patient's seminal fluid was examined twice before the treatment, and living spermatozoa were found in great numbers. The x-rays were applied three times. At the end of that time the patient returned, when his semen was again examined twice, and found to contain a few dead spermatozoa. He was then exposed to the rays three times more, and two more examinations of the seminal fluid showed no spermatozoa whatsoever. He was then taken off the x-ray treatment. Three months later his semen was twice examined and found to be full of motile spermatozoa. The restoration was apparently immediate and complete.

Dr. L. Bolton Bangs, of New York, said that since this subject was presented by Dr. Brown some physiological questions had presented themselves to his mind, and he would like to have those who made the obser-

vations, and Dr. Osgood in particular, throw some light upon the subject. He asked if during the disappearance of the spermatozoa there was also an associated loss of sexual desire and a loss of the power of sexual intercourse. It seemed to him that these questions had a rather important bearing, and that they should be answered with some definiteness. He understood Dr. Osgood to say that there was no permanent deterioration in sexual capacity, but that was indefinite.

DR. FRANCIS R. HAGNER, of Washington, D. C., said there was a case in Washington that had come under his observation, being that of a physician who had done considerable x-ray work. This physician had been married nearly two years and his wife had not become pregnant. Dr. Hagner had not examined him, but the physician had examined his own seminal fluid and found no spermatozoa. He then used a kind of lead apron in his x-ray work for a period of four months, at the end of which time his wife became pregnant.

DR. OSGOOD, in closing the discussion, said that in the cases observed there had been no evidence of sexual deterioration in any form. They still retained the sexual desire and the power of sexual intercourse. This was a very important question, and we ought to have as much information in regard to it as possible. He could see how it might be applied to the relief of certain conditions in married life. As to Dr. Keyes' question, he thought that every man observed had taken precautions since that time. They all improved with precautions. He related the case of a man who began x-ray work in 1905, and who did considerable x-ray work for six months without any precautions. In February, 1905, he knew there were no spermatozoa in the seminal fluid. In June, 1905, there were very few. Several examinations in September and October of the same year showed absolutely no spermatozoa. Examinations were then made once a month until April, 1906, and no spermatozoa were found at any time. Three months later examination showed a few spermatozoa. After the first six months the patient had used very careful precautions. After July, 1905, he was using very careful precautions, but not until after April, 1906, were any spermatozoa found, and then only a very few. In August, 1906, his wife became pregnant, and since that time a very few had been found on repeated examinations. In one case in which improvement had taken place three examinations were made by different men, and each found one spermatozoön. In answer to a question by Dr. Bangs, Dr. Osgood said the patients were all young men, and that no mental effect had been observed. He said he had talked with Dr. Lapowski in reference to the case mentioned by Dr. Keyes, and he thought there was some question as to the amount of protection employed.

DEFORMITIES OF THE PENIS DUE TO SYPHILIS, GONORRHEA AND OTHER CAUSES.

DR. ROBERT W. TAYLOR, of New York, read this paper. This was an important class of cases, concerning which there had been much want of knowledge. Syphilis played an important part in causing such conditions. Others seemed to be an occult symbiosis of syphilis and gonorrhea. Ulceration might occur either in the primary or tertiary stage of syphilis. Indurating edema was seen only in syphilis, most frequently as a complication of chancre. The condition commonly called elephantiasis of the penis was not uncommon in tropical countries, and was also seen in the negroes in the South. It was commonly believed to be due to filariæ, but it was really due to a slow streptococcic infection following gonorrhea or syphilis. No observer, either in America or in Europe, had ever found filariæ in any case of elephantiasis of the penis. Balanitis and phimosis, internal urethrotomy and total extirpation of the inguinal glands might be followed by deforming conditions of the penis.

DR. JOHN H. CUNNINGHAM, of Boston, said he was pleased to hear that Dr. Taylor had found no cases of elephantiasis of the penis to be of filarial origin. Recently in going through the literature while preparing a thesis for this Association he had been impressed by the fact that no case had been proved to be due to filariæ. Although lymph scrotum and elephantiasis of the lower extremities had generally been found to be caused by filariæ, none of the cases of elephantiasis of the penis had been attributed to that cause. It was known that the adult worm occluded the lymphatics, either by its own presence, or secondarily by producing an inflammation which constricts them and produces a dilatation distal to the point of constriction. These dilatations rupturing into the urinary tract would produce a condition of chyluria, etc. He asked if Dr. Taylor could tell whether or not an incision into a penis affected with elephantiasis would bring forth a chylous fluid. He had been unable to find anything on this point in the literature.

DR. TAYLOR said that it seemed to him that the filariæ had been praised for labors not their own. It was a case in which generalizations had been made from a few cases. It was found in southern climates that filariæ would cause abscesses, but the long-continued hyperplasia that was called elephantiasis was undoubtedly caused by the streptococcus. In southern climates a little ulcer would occur, and then this would become infected with the streptococcus. This streptococcus infection was sometimes hereditary, cases having been reported in which children were born with elephantiasis. Chylous fluid was found in one of Dr. Taylor's cases. His studies convinced him that this whole subject had been misunderstood.

PRESENTATION OF INSTRUMENTS.

DR. JAMES R. HAYDEN, of New York, presented (1) an all-metal bladder syringe, that had the advantage that it could be readily sterilized. The piston was of rubber. (2) A modification of Dr. Gouley's tunneled sound, with the tunnel on the concave surface of the instrument, the object of this being to prevent in operations the cutting of the filiform bougie, which might occur with the old instrument. (3) A small bladder aspirator, which could be boiled, and which had the advantage of being very portable, whereas the old trocar and canula was quite a considerable instrument.

DR. EDWARD L. KEYES, JR., of New York, had used the form of syringe presented by Dr. Hayden, and thought it was better than any large syringe he had ever used.

DR. JOHN VAN DER POEL said he was very much interested in Dr. Hayden's guide and tunneled sound. Two or three years ago he had shown a somewhat similar modification with a Benique or Guyon curve. Cases often came to the clinics suitable for the filiform, and in which only a filiform could be passed. The patient would not submit to operation, and the next time he presented himself the stricture would have retracted down to the same size as at first, and it would be necessary to go through the same process of filling the urethra with filiforms, then passing a tunneled sound and stretching the urethra up to 9 or 10 French. He had thought it wise to have made a number of tunneled sounds of different sizes to pass over the filiform, in order to perform rapid dilatation up to 14 or 15 French, after which it was generally possible to pass an ordinary bougie. These sounds ran up as high as 24 or 25 French, and in all of them he had the Benique curve. He had found in per-

forming external urethrotomy that that curve was more practical, as with a strong sound the perineal tissues to be cut through could be compressed until they were not more than half an inch thick, instead of having to cut through a large amount of more or less spongy tissue. In that way it was easier and quicker to cut into the urethra. His instruments did not have the advantage of having the filiform on the anterior surface.

Dr. Harvey G. Mudd, of St. Louis, asked Dr. Hayden if he had found, practically, that it did facilitate the passage of the tunneled sound to have the groove on the concave surface.

Dr. Hayden, in closing, said the only advantage of having the filiform on the concave surface was to avoid cutting it. Sometimes in using the old instrument he had cut the filiform, which, of course, was a rather disagreeable accident. The only claim for merit was that with the filiform out of danger the operation was greatly facilitated.

A successful case of anastomosis between the vas deferens and the globus major, for sterility following gonorrheal epididymitis.

Dr. Francis R. Hagner, of Washington, D. C., reported this case. The patient had had gonorrheal epididymitis on both sides, and before operation examination showed entire absence of spermatozoa. The operation devised by Martin, of Philadelphia, was done, by which an anastomosis was made between the vas and the globus major of the epididymis. An examination of the patient's seminal fluid a month after operation showed numerous spermatozoa, though no pregnancy has resulted. Dr. Hagner also mentioned a case he had seen with Dr. Martin, which Dr. Martin had operated on. This patient's wife had become pregnant since the operation, but had miscarried.

Dr. L. Bolton Bangs, of New York, had had no personal experience with the operation. He had considered it, and was hoping to have the opportunity of doing it, because it seemed to him to open up a wide field of conservatism and of hopefulness for those who were, at present at least, permanently sterile. He wished to know in what percentage of the cases operated on a permanent good result had been obtained.

Dr. Hagner said that Dr. Martin reported 5 cases last year. He thought they were all a success in that they had a return of spermatozoa. Whether there was a tendency to relapse, whether the spermatozoa again disappeared or not, he could not say, as the operation was still in its infancy. In his own case, the spermatozoa had increased at each examination. The last examination, a year after the operation, the semen was loaded with living spermatozoa.

The surgical treatment of sterility in the male.

Dr. Edward Martin, of Philadelphia, said his work during the past year in the operative treatment of sterility in the male had been a series of unbroken failures. He had had no successful case, and yet the reasons in each case were mechanical. All of the cases operated on had active, motile, healthy spermatozoa, but the obstruction was found to be elsewhere than in the epididymis. In one case there had been such a deep-seated inflammation in the epididymis that it was necessary to tap the testicle, and even then no spermatozoa were found, but subsequently they were found when the anastomosis was made He had found that the obstruction was not necessarily confined to the epididymis, but might affect the vas or the ejaculatory ducts. In order to determine whether there was obstruction between the epididymis and the posterior urethra, the vas was opened and some one of the soluble dyes injected into it. If the vas was patulous, the dye would appear in the next ejaculation. All the cases operated on during the past year failed to show any sign of the dye after this test, showing obstruction above the epididymis. The operation could be done perfectly under local anesthesia, without interfering with the patient's work. An important point in the technique was the handling of the veins very gently, in order to prevent phlebitis. After mumps there was apt to be so much atrophy that the operation was not available. He had demonstrated that where the conditions were favorable the operation was not only successful, but it apparently remained permanently so. There seemed to be no tendency to close up. Some of the cases had existed for several years, and active spermatozoa were still found. It was desirable before the operation to get rid of the chronic posterior urethritis which usually accompanied these old cases of epididymitis.

Dr. John van der Poel asked if Dr. Martin did not report last year one case where the wife had become pregnant after the operation.

Dr. Edward L. Keyes, Jr., of New York, asked Dr. Martin if he tapped the vas posteriorly.

Dr. Martin said he had reported a case last year in which the wife became pregnant after the operation. It was the case mentioned by Dr. Hagner. The proof seemed to be complete. The vas was reached by the shortest route, which was the posterior. The tunica vaginalis was cut through, and the whole of the epididymis exposed. With a pair of forceps, of the kind used by eye specialists, a portion of the epididymis was picked up and snipped out with a pair of eye scissors. If spermatozoa were present, a characteristic drop would appear in the wound. This was examined microscopically and reported on. If spermatozoa were not found, one should go a little higher up and a little deeper in. The openings were closed by a very fine stitch. A most surprising feature was that a man who had never had a vas had motile and healthy spermatozoa. Closure of the duct was not followed by atrophy in this particular case. Also, the fact was corroborated that spermatozoa were motile before they were mixed with the prostatic fluid. The spermatozoa did not need for their full development the passage through the epididymis, nor admixture with the prostatic fluid.

Spontaneous fracture of calculi.

Dr. Arthur T. Cabot, of Boston, said the subject of spontaneous fracture of stones had always interested him, and two years ago, when he was in England, he looked over the beautiful collection of calculi at the Norwich Hospital, and was perfectly astonished to find about a dozen first-rate instances of spontaneous fracture in that comparatively small collection of stones. Spontaneous fracture was a characteristic of uric acid stones, or of a combination of uric acid with other substances. In stones of other constituents spontaneous breaking up took place only from without inwards, through solvent action, and the fragments did not show any of the characteristics of true spontaneous fracture. Oxalates often broke spontaneously, but never showed regularity in their fragments. Spontaneous fracture of uric acid stones was due to the arrangement of the crystals in the building up of the stones, and even the smallest stone showed a characteristic segmentation. The nucleus of a uric acid stone was always separated from the body of the stone by a layer of urate of ammonia. From this layer furrows and ridges extend toward the periphery. The presence of these furrows and ridges was the real arrangement which made for spontaneous fracture. The rifts and ridges might also start from layers more distant

from the nucleus. It was only in exceptional cases that the nucleus fell away together with the other layers. Spontaneous fracture took place most successfully in the bladder since it was brought about in stones in the renal pelves only very rarely. Chemical action might be explained as a factor through the solution of the substances in the furrows or rifts, to allow of which it must be supposed that all or some of the rifts reached to the surface of the stone and were exposed to the action of the urine in the bladder. Spontaneous fracture was rather apt to take place in a urine which, having been concentrated, had become very dilute. It seemed as if this extremely dilute urine, filtering into the stone along these rifts or radiating striæ, dissolving the more soluble parts of the stone, freed the less soluble parts, and they became separated in the form seen in the photographs. Dr. Cabot said it was a revelation to him that spontaneous fracture was so frequent as he found it to be at Norwich. It was certainly very rare in this country. The stones found in this country were mostly secondary phosphatic stones, due to alkaline fermentation of the urine. Unfortunately, the present habit of crushing stones might destroy a good many good specimens of spontaneous fracture.

DR. RAMON GUITERAS, of New York, had had one case of spontaneous fracture of vesical calculi, which he had presented at the Academy of Medicine in New York. In this case there had evidently been three or four stones in the bladder. The bladder walls were found to be very much thickened, and the breaking up of the stones had probably been caused by the pressure of the bladder walls upon them. The diagnosis had been made of stones in the urethra. On operation through the perineum it was found that there were three calculi in the posterior urethra. When the bladder was opened it was found to be literally full of stone fragments, and 100 to 150 pieces were removed through the perineal wound.

DR. JAMES BELL, of Montreal, mentioned a case that had interested him very much a number of years ago of spontaneous fracture of stones in both kidneys. A stout, beer-drinking Englishman, about thirty-five years of age, came into his hospital service in a very bad condition. He had chills, high fever, scanty, purulent urine, and marked tenderness over the kidney regions. A diagnosis of renal calculi was not thought of, the condition being attributed to an infection of some sort. The patient's condition would not permit of an operation, and he died in about forty-eight hours after entering the hospital. Autopsy showed the pelves of both kidneys full of stone fragments. As the stones were not analyzed, he could not say what their composition was. The finding of the fragments was a great surprise, as at that time he had not heard of such a condition.

DR. L. BOLTON BANGS, of New York, said that when the advertisement of Buffalo Lithia Water first appeared, declaring that spontaneous fracture of stones in the bladder was possible, he, of course, ridiculed it, but subsequently at an operation where he did a suprapubic cystotomy for the removal of stone the appearances were such that he began to suspect that such a thing was possible. The majority of stones seen in practice in this country were those which might be termed secondary stones. But the appearances of the stones mentioned were such that it seemed to him the question of spontaneous fracture of stone in the bladder had not been given enough attention, and that such a thing was possible. It was a revelation to him to learn that there could be so many of such cases.

DR. HUGH H. YOUNG, of Baltimore, said this was an interesting topic, and one that had been very much neglected in the past. His attention was called to the subject several years ago, owing to a case he had then. An old gentleman suffering from enlarged prostate came to him, after spending six weeks at the Saratoga Springs. He came for operation, and a cystoscopic examination was made preparatory to operation. He was startled to find stones broken up in his bladder. This made a most beautiful cystoscopic picture. The fragments were removed by an evacuator, as after lithalopaxy, and 19 fragments were found that were beautiful specimens of fractured calculi. They agreed with Dr. Cabot's description, in that the nucleus removed did not participate in the fracture. In looking over the literature he was struck by an extensive series of articles in which the author had come to the conclusion that the fracture of the stones was due to a change in the composition or character of the urine, as Dr. Cabot had explained. Dr. Young's case bore out that contention. The patient went to Saratoga and lived six weeks, and evidently the fracture was produced by drinking that water. Enough attention was not paid to the hydrotherapeutic treatment of cases of calculus, either before or after operation.

DR. EDWARD L. KEYES, JR., of New York, asked Dr. Cabot as to the practical bearing of this subject. It was suggested to him by Dr. Bangs's remarks concerning the Buffalo Lithia Water. He said they had a collection at their office of over 200 stones, and yet they had no record or evidence of any spontaneous fracture in the bladder. This would bear out Dr. Cabot's statements as to its rarity in this country. He had his eye kept open for a record of a case in which the fragments of a stone spontaneously fractured had been passed spontaneously, but he had not been able to see that it made any difference in the treatment whether the stones were fractured or not, they were not passed, and the condition of the patient remained the same. Therefore, water as a means of producing spontaneous fracture of stones was totally valueless.

DR. CABOT, in closing, said he did not think these observations as to spontaneous fracture could be taken as proving the value of Buffalo Lithia Water, because the stones could be removed so easily and thoroughly by mechanical means. It would be very rare indeed for a stone of any size to break up into fragments small enough to pass through the urethra. He did think that waters were very valuable after operations, for stone and to dissolve beginning stones. He has had cases which convinced him that stones in the kidney were dissolved.

(To be continued.)

Book Reviews.

Principles and Practice of Dermatology. By W. A. PUSEY, A.M., M.D. New York and London: D. Appleton & Co. 1907.

We have read this new dermatological textbook of a thousand pages with special interest and find in it very much to commend. As the writer states, more space than usual has been given to the principles of dermatology; also general treatment has been very fully dealt with. Much space is given to some of the affections with which the writer has had special experience; for instance, blastomycosis. The chapter on this affection is admirably written and is accompanied by a number of excellent illustrations. The re-

markable frequency of this affection in Chicago has afforded the author an opportunity to discuss the disease more intelligently than could de done by a writer from another city. Most of the illustrations are of great excellence. Rather less space than usual is given in this book to the microscopic anatomy of cutaneous affections. The author's well-known experience with x-ray therapeutics makes his comments on this method of treatment and its practical application of great interest.

Medical Diagnosis. A manual of clinical methods for practitioners and students. By J. J. Graham Brown, Assistant Physician, Royal Infirmary of Edinburgh, and W. T. Ritchie, Clinical Assistant Pathologist, Royal Infirmary of Edinburgh. New York: Imperial Publishing Co. 1907.

This manual of clinical methods has reached its fifth edition, an evidence in itself of a demand for the book. It is comprehensive in that a survey of both the theory and practice of the methods of physical diagnosis as well as clinical laboratory procedures is attempted in a book of very moderate size. This fact of course entails a scantiness of detail in many parts, but on the whole the choice of subject matter has been good and the result is a compact book containing much information, especially useful for the student beginning his study of clinical methods.

The book is well printed and mistakes are very few. The use of " stones " as a measure of weight is to be criticized in an American published book. Again the authors' condemnation of the binaural stethoscope and advice to use a simple wooden stethoscope is out of harmony with American usage. The use of the word " cirrhotic " in reference to the kidney is etymologically incorrect as is also " mammary " instead of " mamillary" line. Under the consideration of abdominal palpation the method of palpating with the patient in a warm bath should be included as a very helpful procedure in some cases in which general anesthesia might otherwise be required. On page 98 the impression is given that the standard in the Haldane hemoglobinometer is a 1% solution of hemoglobin instead of a solution of carbon monoxide hemoglobin. On pages 116 and 117 the authors' distinction between the lymphocytes included under pathological leucocytes and normal lymphocytes is not clear and a somewhat more extended account of the general histogenesis of blood cells would perhaps give a better idea of blood conditions than is obtained from the authors' account.

However, these criticisms are not intended as a condemnation of the book. In the main they apply to points of minor importance and the book is to be commended within the limitations set by its scope and size. The consideration given to graphic methods of studying venous and arterial pulses is in keeping with the present active interest in this method of study. The inclusion of a description of opsonins indicates that revision has kept the book up to date.

Diseases of Women. A clinical guide to their diagnosis and treatment. By George Ernest Herman, M.B. Lond., F.R.C.P. Consulting Obstetric Physician to the London Hospital; Consulting Physician-Accoucheur to the Tower Hamlets Dispensary; Late President of the Obstetrical Society of London and of the Hunterian Society, etc. With 265 illustrations. New York: William Wood and Company. 1907.

This is a book of 900 pages and of convenient size to handle. It is legibly printed on good quality paper, except that the plates of the illustrations are worn and therefore the figures are not as distinct as in the earlier editions. Gynecology is approached from the standpoint of symptomatology as the following chief headings from the table of contents show: General; Chronic Pelvic Pain; Pelvic Inflammation; Internal Hemorrhage; Hemorrhage; Leucorrhea; Disorders of the Vulva; Disorders of Menstruation; Disorders of the Sexual Functions; Disorders of Parts Adjacent to the Sexual Organs; Abdominal Tumours.

The book is not a compilation of the work of others, nor yet a system. It represents for the most part the views of a practitioner of mature experience and somewhat from the obstetrician's standpoint. It is intended for the general practitioner and not for the specialist. As to the relations of the family doctor to minor gynecology the author says (p. 5): " The minor gynecological ailments, real or supposed, are common, and the majority of them came first to the family doctor. We can by sound advice prevent the patient from magnifying trifles; can disabuse her of erroneous theories before they have become fixed in her mind; can dispel her fears for the future; can correct an unhealthy mode of life before it has had time to do harm. He can render these great services to his patients more easily than a specialist, because he knows more about his patients, is called in earlier, and sees them oftener." Also: " Major gynecology must always be reserved for the specialist."

Supplemented with a good American text-book for the technique of minor gynecology this is a valuable volume for the physician's library.

A Handbook of Skin Diseases and Their Treatment. By Arthur Whitefield, M.D. (London), F.R.C.P. New York: Longmans, Green & Co. London: Edward Arnold. 1907.

The writer asserts in his preface that although there are many large treatises on dermatology, he believes there is still place for a concise book for students and general practitioners, and this has been the object of this work. Treatment is especially dealt with, and on this subject the writer is particularly clear and practical. The new methods of Sir A. E. Wright are dealt with, probably for the first time in an English text-book. The photographs and micro-photographs in this book are of special excellence.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 8, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

FEES FOR LIFE INSURANCE EXAMINATION.

WE have on various occasions alluded to the policy of the large insurance companies in reducing the fees for medical examination. Throughout the investigations which have recently brought the companies prominently to public notice it has been evident that the medical profession in its intimate relations with insurance corporations was likely to be a co-sufferer. This proved, at least temporarily, to be the case in the attempt to reduce the fees for medical examinations. The protest against such a reduction has been widespread and emphatic with results which are just now manifesting themselves.

It will be a gratification to the medical profession to learn that very recently two of the three large New York Life Insurance Companies, the Mutual Life and the Equitable, have notified their medical examiners that after Aug. 1, 1907, these companies will pay a fee of five dollars for each examination for new insurance, irrespective of the amount of insurance applied for. The five-dollar fee had been paid by these companies from their origin, since 1843 in the case of the Mutual Life, and it seemed unjust to cut down the schedule at a time when wages and salaries throughout the industrial world had been steadily rising and living expenses at the same time increasing.

For the first time in history a powerful corporation was met by an organized resistance of the medical profession throughout the country, led by the American Medical Association. A very large number of the County Medical Societies, especially in the South and West, passed resolutions denouncing the fees as inadequate, and their members agreed to make no examinations for less than five dollars. As a result, the companies lost a large number of their best examiners and in certain sections their business was brought to a complete standstill.

In this unhappy controversy the companies feel that their attitude has been greatly misunderstood, claiming that they adopted the new fee schedule reluctantly, feeling that it was necessitated by the strong demand for economy which applied especially to cost in obtaining new business, the New York legislature establishing a sharp limitation and making it a criminal offense to exceed this. All the items which entered into this first year's expense were materially reduced, among them being the medical examiner's fee. The law did not wholly go into effect until Jan. 1, 1907. At the end of six months' trial, the companies announced that their economies had been greater than necessary and there was in consequence a small unexpended surplus. Appreciating the medical examiner's work and his value to the company, as soon as it was demonstrated that this surplus existed, the companies gladly restored the old fee to the examiners.

Recognizing the delicate situation in which the medical directors have been placed, we do not desire to criticize their explanation. At the same time, the medical profession may justly feel satisfaction at the successful outcome of a contest which has upheld its dignity and developed a significant *esprit de corps*.

In view of all the facts, it is certainly unfortunate that any representative insurance company should maintain the reduced fees for medical examinations. It is impossible to urge that the recognized fee of five dollars is unfair or exorbitant for the service rendered, which naturally consists not only in the examination of a candidate for insurance but also in the rendering of an expert opinion as to his physical condition. It is perfectly apparent that, if life insurance is to be restored to the place of dignity which it has of late been in danger of losing, the medical examination must be regarded as significant and the medical examiners must be treated with the consideration which the character of their work demands. It should therefore certainly be a matter of gratification that the large insurance companies, with one striking exception, are reverting to a scale of fees which has been justified by long experience and which medical men serving in the capacity of examiners have a most legitimate right to demand shall be maintained.

THE PROGNOSIS AND THERAPEUTIC MEASURES IN CHEYNE-STOKES'S RESPIRATION OCCURRING IN THE NEPHRITIDES.

The prognostic value of Cheyne-Stokes's respiration in the various nephritides is very variable, according to different writers. For some, this phenomenon not only indicates a fatal issue, but even an imminence of the end. Such is, particularly, the opinion or Traube, Merkel, Ziemssen and Biot. Saloz is more inclined to believe that the prognosis depends both on the nature and the intensity of the causal lesion and on the condition of resistance of the indivdual, while Hallopeau, Petit, Rendu and Merklen incline to this view. Out of fifteen cases recorded by Maillard in his thesis, eight presented a periodical dyspnea preceding death within a few days, while in other cases Cheyne-Stokes's respiration was present for a few days, then regressed and was followed by a period of calm for a certain length of time. It should be pointed out, however, that intermittent dyspnea finally reappears at more or less prolonged intervals, only to end in the final period preceding death.

This variance in the evolution of Cheyne-Stokes's respiration in nephritis is due to the productive lesions and the prognosis should consequently be made from a knowledge of these causes. There may be lesions of cardio-arterial insufficiency, or, on the other hand, the cardiac muscle may not be involved, in which case Cheyne-Stokes's is merely an epiphenomenon, destined to disappear with the asystolia, which gave rise to it. On the other hand, when the cardiac muscle is affected in its anatomical integrity, the prognosis is serious, because the heart can no longer overcome the valvular insufficiency, and consequently ischemia is inevitable and becomes more and more marked.

In instances where the predominating lesions are due to an arterio-sclerosis, the prognosis is serious, but not fatal, depending in a large measure on the condition of the heart. Blood irrigation is defective and has become permanent on account of the pathological cause, but the heart may partially overcome this functional insufficiency for a variable length of time, by an increase in its activity. However, the time comes when the cerebral ischemia increases on account of the cardiac insufficiency, serious symptoms appear, including Cheyne-Stokes's respiration, and death soon occurs. And lastly, in those cases where cardiac and vascular lesions co-exist, the prognosis is bad, and here Cheyne-Stokes's phenomenon indicates approaching death.

Generally speaking, the condition of the heart should guide the prognosis and, if this muscle has preserved its anatomical integrity, nothing need be feared for the time being; but if, on the contrary, there is arythmia, the outcome is serious.

The knowledge of the causes of Cheyne-Stokes's respiration should guide us in the treatment. Rendu and Merklen have used digitalis with the hope of diminishing the cerebral ischemia by increasing the functional activity of the heart, but their results have been variable. Sometimes Cheyne-Stokes's respiration disappeared, while, on the contrary, in other instances, its intensity increased, and this is probably due, as Merklen has pointed out, to the vaso-constricting action of the digitalis. The administration of this drug should find its principal indication in those cases of Cheyne-Stokes's respiration due to functional cardiac disturbances of an asystolic nature, in which the muscle is worn out, but not degenerated and so has need of the tonic effect of digitalis. But every time that the cardiac muscle has become so changed as not to react to this drug, it is absolutely contra-indicated, and one should endeavor to facilitate to the utmost the work of the heart. This may be obtained by milk diet, various diuretics and caffein, and the diuresis produced and kept up by these measures diminishes the overcharge of the circulatory system and the heart's work.

When Cheyne-Stokes's respiration is due to generalized arterio-sclerotic lesions, and if the cardiac muscle is not pathologically changed, it is quite permissible to counteract the arterial insufficiency by the administration of digitalis, which will increase the contractile energy of the heart. The ischemia resulting from the vaso-constriction need not here be feared, since the walls of the arteries, pathologically changed in their intimate structure, will react in a lesser degree. One may also employ the ordinary treatment of arterio-sclerosis, such as the iodides and a milk diet, and this would seem a useful therapeutic indication, especially in those cases where it is no longer possible to act on the heart.

And lastly, if there is a coincidence of cardiac and advanced arterio-sclerotic lesions, the causal treatment is no longer possible, and here the use of morphine becomes the one of choice in the treatment of the Cheyne-Stokes's phenomenon. When properly used this drug may occasionally regulate the respiration and give the patient sufficient rest. This remarkable action of morphine has been known for a long time and Weber, Saloz, Frentzel, Rendu and Pic have all noted the happy

influence of this drug, which, by the vaso-dilatation it produces, favors the afflux of blood to the cerebral vessels, so that it may be said that, in those cases where digitalis or the treatment of arterio-sclerosis have failed, hypodermic injections of morphine will be a valuable adjuvant in the treatment of Cheyne-Stokes's respiration in nephritis.

INSTITUTES FOR MEDICAL RESEARCH.

THE sixth volume of studies from the Rockefeller Institute for Medical Research has an added interest from the fact that it contains a description of the new buildings of the institute, together with the addresses delivered at the opening of the laboratories in New York, May 11, 1906. At present the Rockefeller Institute embraces three independent buildings, the chief of which is the laboratory building. Owing to its situation on a high bluff fifty feet above tide water, overlooking on one side the East River, this building has unobstructed light in all directions, and owing to its somewhat isolated position is also remarkably free from the disturbing noises of a great city. The laboratory building measures one hundred and thirty-six by sixty feet, and is five full stories in height. It is hardly necessary to say that the internal arrangements are constructed to meet the most modern requirements of laboratory research, particularly in its experimental aspects.

Now that this great institute, to be devoted solely to medical research, has become a reality, the natural question arises, and will surely arise often in the future, whether the establishment and development of institutes of research separate from established educational institutions is the best way to promote progress. The Rockefeller Institute has already justified its existence through a large amount of admirable, original work, which has proceeded from its students, and it is not to be questioned that the means will be forthcoming to extend this work in the future as occasion may demand. In general, however, the establishment of such independent institutes, except under the most favorable conditions, seems unwise and for the following reasons: In the first place, the cost of maintenance is very much greater for such an independent work than if associated with a pre-existing foundation. In the second place, the organization of the work is complex, and the difficulty of obtaining workers of experience and education considerable. In the third place, it is increasingly important that the various branches of medical science should be brought into closer relationship, as knowledge in each grows deeper. For these reasons, it is, on the whole, desirable that there should at least be a limit to the number of separate institutes, of which the Rockefeller Institute for Medical Research is one of the most notable examples. It is to be hoped that in the future great public benefactors will give toward the development and maintenance of existing institutions in close affiliation with university foundations, rather than establish more independent centers of research, which, however equipped and manned, must be handicapped by certain limitations which would not be the case under a general university administration.

MEDICAL NOTES.

CENTENARIANS. — The death of Mrs. Harriet B. Farrie, of Somerville, Mass., is announced at the age of one hundred years. Mrs. Sarah T. Robinson, of Lynn, Mass., has recently died at the reputed age of one hundred years.

RAILROAD CASUALTIES. — According to a recent accident bulletin, the three months ending March 31 have had an appalling number of accidents, although somewhat less than during the previous three months. The total number of accidents to passengers and employees was 20,563. Of these 421 persons were killed. There were 3,991 collisions and derailments, of which upwards of 500 affected passenger trains. The money loss amounted to more than three million and a half dollars.

DEATH OF DR. WILLIAM T. HOWARD. — Dr. William T. Howard has recently died at the age of eighty-six. Dr. Howard filled the first chair in gynecology established in this country at the University of Maryland, where he was a professor for thirty years. He was one of the founders of the American Gynecological Association and its president in 1884 and 1885.

A PRACTITIONER FOR SEVENTY YEARS. — Dr. William Bayard, of St. John, N. B., completed seventy years of professional activity on August 1. Congratulatory messages were received by him from the University of Edinburgh, where he received his medical degree, and from various medical societies with which he has been associated. A personal letter was received from the president of the Dominion Medical Association, a position which Dr. Bayard himself had formerly occupied.

Typhoid Fever in the Philippines. — Typhoid fever, according to the *Report of the Bureau of Health for the Philippine Islands*, seems to be obtaining a firmer foothold in the Philippines than has heretofore been the case. As the changes which ordinarily accompany an introduction of modern improvements are more and more introduced in these islands, it is becoming more apparent that this disease is constantly affecting more persons. At the present time the construction of the new railroads in the Islands is responsible for the gradual introduction of typhoid in many places at which it has not been encountered heretofore. Fortunately, so far the disease has apparently been due to direct importation, cases having occurred among Americans and Japanese who have only recently come to the country, and either arrive in the incubation period or have ingested infected foods obtained in the countries from which these new arrivals come. Filipinos seem to be the victims only in so far as they come in contact directly or indirectly with the former nationalities. Almost fifty cases have come to the knowledge of this Bureau during the quarter. It seems probable that the reasons why typhoid has not spread more heretofore in the Philippines are not so much because of the tropical climate, but because the ordinary vehicles by which the disease spreads have not been present.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, August 7, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 24, scarlatina 21, typhoid fever 16, measles 38, tuberculosis 68, smallpox 0, leprosy 0.

The death-rate of the reported deaths for the week ending August 7, 1907, was 20.19.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Aug. 3, 1907, was 224, against 238 the corresponding week of last year, showing a decrease of 14 deaths and making the death-rate for the week 19.16. Of this number 130 were males and 94 were females; 220 were white and 4 colored; 153 were born in the United States, 62 in foreign countries and 9 unknown; 39 were of American parentage, 170 of foreign parentage and 15 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 38 cases and 3 deaths; scarlatina, 21 cases and 0 deaths; typhoid fever, 17 cases and 2 deaths; measles, 37 cases and 1 death; tuberculosis, 66 cases and 25 deaths; smallpox, 0 case and 0 death. The deaths from pneumonia were 13, whooping cough 5, heart disease 22, bronchitis 0 and marasmus 4. There were 22 deaths from violent causes. The number of children who died under one year was 53; the number under five years, 15. The number of persons who died over sixty years of age was 35. The deaths in public institutions were 78.

There were 2 cases and 4 deaths reported from cerebrospinal meningitis during the week.

Tetanus a Reportable Disease. — The Massachusetts State Board of Health has recently added tetanus and chicken-pox to the list of reportable diseases. It is hoped by placing tetanus in this list that more complete observations may be made upon the disease than have hitherto been possible.

Davis Memorial Fund. — Contributions in this state to the Davis Memorial Fund have been received by Henry O. Marcy, chairman of the committee, in the sum of $618. This amount has been remitted to Dr. Frank Billings, of Chicago, treasurer of the committee. It is hoped that more contributions will be forthcoming.

Boston Insane Hospital. — The admissions to the Boston Insane Hospital, according to the tenth report of that institution, for the year ending Sept. 30, 1906, were 316, 125 men and 191 women, which is 100 less than the preceding year. In spite of this fact, the daily average of the year was 701, as compared with 671 the preceding year. A study of the statistics shows that 30% of the admissions to this hospital were sixty years old or over, a percentage exceeded in Massachusetts only by the wards for insane patients at the State Hospital at Tewksbury. A plea is made in the report that more land be purchased and that additional buildings for men be constructed. The further recommendation is made that a small emergency hospital be established for cases of mental disease, bearing the same relation to the Boston Insane Hospital that the Relief Station bears to the City Hospital.

NEW YORK.

Typhoid Fever at New Jersey State Asylum. — On July 29 the Board of Managers of the State Asylum for the Insane at Trenton, N. J., appointed as medical director of the institution, Dr. Peter P. Rafferty, of Red Bank, chairman of the medical committee of the board, in the place of

Dr. John W. Ward, removed. During the past spring at least twelve cases of typhoid fever occurred in the asylum, and an investigation has shown the premises to be in a very bad sanitary condition.

AN EPIDEMIC OF SORE THROAT AT SAG HARBOR. — The town of Sag Harbor, Long Island, is suffering from a severe, though apparently not dangerous, epidemic of sore throat, the exact nature of which is not stated, and nearly the entire population is affected by it. The season has been a very dry one, and the trouble is attributed by the physicians of the place to the clouds of dust, caused by numerous automobiles. The whole of Long Island is much frequented by these vehicles, and while the practice of sprinkling the roads with crude petroleum to lay the dust is in general use in many parts of the island, it does not seem to have been adopted as yet in its eastern portion.

A CENTENARIAN.— Mrs. Catharine Gilligan, believed to have been the oldest woman in the Borough of the Bronx, New York, died on July 30, at the apparently authenticated age of 107 years. She was born in County Sligo, Ireland, on St. Patrick's Day, March 17, 1800, and came to this country about twenty-five years ago. Her death was due simply to old age, and she is said to have prided herself on never having taken a drop of medicine in her life. She had eight children, twenty-four grandchildren, five great-grandchildren, and two great-great-grandchildren.

ST. BARNABAS' HOSPITAL. The annual report of St. Barnabas' Hospital at Newark, N. J., recently published, shows that 1,028 patients were cared for during the last year in the wards and private rooms, and about 4,000 treated in the out-patient clinics. The endowment fund of the hospital has now been increased to $100,000.

WARFARE AGAINST MOSQUITOES. — On July 31 the Board of Health held its regular weekly meeting on board the *Governor Flower*, the official cutter of Dr. Doty, Health Officer of the Port, while the vessel was steaming through the East River on its way to various points in the Borough of Queens, where there are salt marshes and many mosquitoes. On the way Dr. Doty gave some account of the warfare against the mosquitoes of Staten Island, which he has been waging for the past three years, and of the gratifying success which has attended his efforts at extermination, and the board determined upon certain measures to be adopted against the Long Island pests. Appropriations of considerable amount have been promised by the municipal authorities, with which to carry on the campaign, and it is proposed to enforce a law passed a year or two ago, which compels known private owners of salt marshes to ditch their own property.

RETIREMENT OF A POLICE SURGEON. — Dr. Stephen G. Cook, who was for many years a police surgeon, and for a considerable period president of the board of surgeons, was retired from the force on July 27, and will receive a life pension of $1,750.

RULE REGARDING FEES AT BELLEVUE HOSPITAL. — The Board of Trustees of the Bellevue and Allied Hospitals have just established a new rule which requires that any patient admitted to any of these public hospitals, who is possessed of funds of more than $50, shall have deducted from such funds, on discharge, $1.50 for each day's treatment. It is expressly provided, however, that this deduction shall not diminish the amount returned to a patient to a sum less than $50. Some objections having been expressed to this regulation, on the ground that it was unjust to enforce such a rule in institutions supported by the city, Dr. Armstrong, medical superintendent of Bellevue, has made a statement in which he says that the Board of Trustees found that a number of patients who could well afford to pay for treatment in some of the other hospitals were being treated in Bellevue, and its allied institutions, at no cost to themselves. In view of this fact and in order to prevent the needy poor from being crowded out of the beds — and from the further fact that the charter of Bellevue requires it — they adopted the rule mentioned. There is a law in the city which punishes by fine any person who can afford to buy medicines, should he go to one of the free dispensaries and get medicine for nothing, and be detected in the act. There is no more reason why the dispensaries should be so protected than that the hospitals should, especially as both kinds of institutions were established for the needy, and not for those who can afford to pay for treatment.

CONVICTION OF A CHRISTIAN SCIENTIST. — In the Court of Special Sessions on August 2, Clarence W. Byrne, the Christian Scientist, who some time ago was convicted on the charge of failing to provide medical attendance for his daughter, a child of six years, who died on May 1 from bron-

cho-pneumonia, was sentenced to thirty days' imprisonment in the penitentiary. The conviction was secured under Section 288 of the Penal Code, which makes it a misdemeanor for a person to "wilfully omit, without lawful excuse, to perform a duty by law imposed upon him, to furnish food, clothing, shelter or medical attendance to a minor." The imposition of the sentence had been postponed in order that certain objections might be filed by counsel for the defense, but, after due consideration, these were over-ruled by the court. At the time sentence was pronounced an opinion was given by Justice McKean, Justices Mayo and Deuel concurring, to the following effect: "The sole question is whether the omission to furnish medical attendance under the circumstances constitutes a 'lawful excuse.' To answer that question by granting the motion in arrest of judgment would establish a precedent that might be extremely vexatious in other directions. An individual of some other cult, with equal plausibility and earnestness could plead disbelief in educational methods as an excuse for not sending children to school; could withhold food, clothing and shelter, leaving each, as part of his religion, to be furnished through the same or similar agency. Certainly the health and morals of children, sought to be conserved as a public benefit, come as naturally within the plea here as do the facts set up by the defendant by the way of justification. The difference between health and education is that one is physical and the other mental, but surely none will seriously contend that this differentiation measures or limits the potency of prayer."

7. Bishop regards physiological re-education as of great value in the cure of functional cardiovascular disease. There must be persistent measures undertaken, covering weeks, months or even a year; but excellent results may be obtained even where compensation is destroyed. The first thing to accomplish is relief from worry and mental concentration for the patient. Next comes reduction of diet, including taking away of the sweets and red meats. Exercise should be carried on systematically, whether the patient wants it or not, except in those cases in which failing compensation necessitates a short time in bed.

New York Medical Journal.

8. McKenna, J. A. *The Comparative Innocuousness of Foreign Bodies in Three Instances.*

1. Eliot describes the occurrence of subcutaneous rupture of the normal spleen (apart from injury to infectious or other enlarged spleens), resulting usually from direct violence, but sometimes also by contrecoup, or from falls on the feet from a considerable height. The rupture may be a simple laceration, or the organ may be reduced by contusion to a pulpy mass. The symptoms depend mainly upon the amount and rapidity of hemorrhage. Respiration is usually thoracic and there is nearly always tenderness and marked rigidity over the upper part of the left rectus and costal arch. The area of dullness extends down into the flank in proportion to the amount of hemorrhage. Resistance to depression by pressure of the eleventh and twelfth ribs, which are rarely fractured, will be present if rupture of the spleen has taken place. The most satisfactory treatment is splenectomy, the technic of which is described. Numerous cases prove that the spleen is not necessary in the bodily economy. Certain cases, it is true, have been slow in recovery and have suffered from anemia and emaciation, but these effects have been rare.

2. Conner mentions a number of auscultatory findings more distinctly obtainable by the naked ear than by the stethoscope. In 8 cases of aortic regurgitation diastolic murmurs almost or quite inaudible with the stethoscope were plainly heard with the ear alone. More important than these he regards cases in which bronchial breathing can be detected only by the naked ear, as examples of which he mentions instances where the diagnosis of pneumonia could be made a day earlier than by the stethoscope. In general, faint, high-pitched sounds are much more plainly heard by the ear alone.

4. Ripperger's article is an exhaustive accumulation of evidence that saccharin as used for sweetening effect is entirely harmless and without physiological action.

1. Taylor describes with illustrations the condition of indurating edema of the vulva, a condition which he believes to be too little recognized. It is almost always due to syphilis, most commonly as a complication of the hard chancre but sometimes as a late lesion; a few cases have seemed to result from chancroids or herpetic lesions. A hard, non-pitting induration of the vulva, more or less extensive, is the result. Antisyphilitic treatment if begun early may cause complete disappearance, but otherwise the swelling persists indefinitely. Some cases go on to atrophy with marked deformity, kraurosis vulvæ, elephantiasis, gangrene and phagedema.

6. Baker protests against the common practice of deferring the treatment of strabismus in children until the patients are able to read test type. In 75% of the cases the condition develops before the fourth year, and in a large proportion the onset is gradual. At first it is only occasionally present; in the second stage it is more or less constant but alternating between the two eyes; finally it becomes constant and monocular. Some cases recover spontaneously. In the first stages often the use of atropine for a few days in both eyes will effect a cure. If this fails, glasses must be prescribed at once by retinoscopy; the author has fitted glasses with most satisfactory results in children less than a year old. In the second stage, that of alternating squint, the results of correcting errors of refraction are also very satisfactory in overcoming strabismus. In older children great patience is often required in efforts to restore the fusion sense, using prisms and decentered lenses, atropin long continued, and insisting upon avoidance of close work for the eyes. The occlusion bandage should be given a trial. If these methods fail, operative treatment is necessary. The author, however, rarely operates on children under ten years of age, and regards operation as a confession of defeat.

8. Tinker calls attention to the occurrence of gall-duct obstruction from the pressure of a movable kidney. He cites two cases, in one of which was found a distended gall-bladder for which no cause could be found except that the right kidney was in a position where it might easily press on the ducts; in the other case it is not proved that the symptoms had anything to do with the biliary tract; both cases were relieved by fixation of the kidney. The author's technic of kidney fixation is described, essential features of which are separation of attachments to the colon, suturing the split capsule to aponeurotic structures in the incision and keeping the patient on the back or the right side for two weeks after the operation.

9. Jones describes cases of thoracic diseases in which the symptoms were referred so positively to the abdomen that it was, or might well have been, believed that acute abdominal disease was present. The conditions mentioned include pleuritis, pneumonia, empyema, aneurysm of the heart, angina pectoris and aortitis.

10. Folin's article is a searching review of the origin and development of the theory of acid intoxication in diabetes, from the early observations of β-oxybutyric acid by Stadelmann and of acetone and diacetic acid by v. Jaksch in 1883, to the recent studies of Knoop, Embden, Baer and Blum. The presence of β-oxybutyric acid, diacetic and acetone being unquestioned, these later investigators have attempted to trace their evolution. Knoop by linking the fatty acids in different stages of oxidation with the benzene group was able to arrest the process in certain intermediate stages, and to test the results by feeding them to dogs. From this work he reached the conclusion that only those fatty acid side-chains from which the carbon atoms can be split off two at a time can undergo oxidation in the animal body. Oleic, palmitic and stearic acid can thus give rise to but one molecule each of oxybutyric acid, whereas caproic acid can yield three, and butyric acid four. Embden passing these substances in aërated blood through excised livers, and Baer and Blum feeding them to patients, all reached confirmatory results. It is probable that the amino-acids which form from proteids can also produce acetone bodies. Much, however, remains unexplained, even if these findings are accepted. Why does the oxidation of carbohydrates diminish the formation of acetone bodies? why do not lactic and oxalic acids play a part in the assumed acid intoxication? and why does not the alkali therapy have more striking results? These questions are not answered.

17. Curtis summarizes the causes of hay fever or hyperesthetic rhinitis as, (1) an adynamic state of the nervous system, the correction of which is important; (2) pathologic changes in the nasal mucosa, such as polypi and deviations of the septum; (3) constitutional disorders such as gout, obesity and disorders of digestion, and (4) external irritants such as gases, dust, pollens, etc. Recently attention has been directed to Dunbar's antitoxin (pollantin) treatment. Opinions received from 34 prominent rhinologists are published, the majority being unfavorable to the claims made for the treatment; a number, however, indorse it. Medicinally suprarenal extracts hold the first place in treatment, in conjunction with constitutional treatment. Climatic treatment is the most efficacious of all. [F. W. P.]

11. HEATH C. J. *On the Duty of Restoring Hearing by Operation in Chronic Aural Suppuration.*

1. Monsarrat reports two cases of sigmoiditis, one chronic adhesive perisigmoiditis, the other subacute in-

filtrative sigmoiditis. In both diagnosis was confirmed by operation. The differential diagnosis from tuberculosis is made chiefly on the absence of tuberculosis elsewhere in the body. From malignant disease it is often impossible to distinguish from clinical signs. Microscopical examination at operation is the only sure method of diagnosis. For treatment of the acute forms he recommends rest in bed with a milk diet and daily enema. For chronic forms, a diet leaving little residue, olive oil enemata for constipation, and astringent rectal irrigation of .2% protargol when there is diarrhea.

2. Brooks speaking on the treatment of appendicitis concludes as follows: (1) The majority of cases will get over the attack if treated on simple medicinal lines. (2) The appendix should be removed during the quiet period. (3) During the attack the patient should be carefully watched and on any sign of fulmination operated on at once. (4) If there be suppuration, if all is going on otherwise satisfactorily, evacuation should be deferred until after the fifth day, care being taken not to open the general peritoneal cavity. If in doubt, operate. No elaborate search should be made for the appendix, it can be removed later. (5) In general suppurative peritonitis, the use of drainage, massive infusions and calomel is advised.

4. Thomas advises what amounts to the Ochsner treatment in perforated gastric and duodenal ulcers; *i. e.*, rest, no food, morphia, no palpation or manipulation of the abdomen, which should be firmly swathed, and washing the stomach free from contents. If operation is done, wipe out stomach contents from the abdomen, drain and leave alone, and do not sew up the perforation or disturb the intestines hunting for it. By this procedure he has been remarkably successful in his cases.

5. Barling has done 39 nephrectomies with one death. He uses the retro-peritoneal lumbar incision and advises a large enough opening to give plenty of room. He prefers to tie off the pedicle by its separate constituents rather than *en masse*. He has never done partial nephrectomy and considers it very rarely advisable.

1. Determann reviews the history of hydrotherapy since its introduction into general medicine, and claims that an extensive plant is unnecessary and that much can be accomplished with simple means at the patient's home. The physician must understand just what physiological changes he wishes to produce and then use his hot and cold applications, compresses, poultices and packs in the various forms which the author describes at some length. Marked changes in the viscosity of the blood can be produced by these simple means, and many chronic and inflammatory processes are favorably influenced thereby.

2. Berger describes two fatal cases of hematemesis in which the autopsy showed superficial erosions of the mucous membrane of the stomach, but no bleeding vessel. In the second case the erosions extended far down into the small intestine. The disease is fairly well characterized, by profuse and repeated hematemesis in patients who have never presented symptoms of ulcer, and by entire lack of gastric pain. It has been described by Dieulafoy under the name of "exulceratio ventriculi simplex."

3. Bittorf calls attention to tenderness of the testicle on the same side as a hitherto undescribed symptom of stone in the kidney. He has observed its presence in several cases of renal calculus, and its absence in gall-stones and abdominal neuroses.

4. The value of Killian's bronchoscopy and tracheoscopy is well shown by Mann, of Dresden, who reports various interesting cases in which the exact diagnosis was possible by this method only. Especially worthy of mention is a case of primary carcinoma of the bronchus, in which the tumor could be seen through the bronchoscope, and a part of it removed through the tube with instruments.

14. The subject of abdominal arteriosclerosis as a cause of serious symptoms is one that has received considerable attention of late. Perutz gives a good critical review of the literature and relates personal experiences. The cases may be divided roughly into two groups: those resembling angina pectoris, and those in which abdominal symptoms predominate. In the former the familiar symptoms of angina appear, only the pain is localized in the epigastrium instead of in the chest. Lighter cases show merely paroxysmal attacks of pain in the epigastrium without the anxiety and dyspnea of angina. The second class of cases presents striking symptoms, consisting chiefly in colic, meteorism and constipation. The greatly distended colon may be plainly outlined against the wall of the abdomen. Physical examination usually reveals tenderness over the vertebral column near the navel, and signs of arteriosclerosis of the thoracic aorta or peripheral vessels. The blood pressure may be greatly elevated during the attacks, as noted by Pal. In some cases, especially those in excessive smokers, there seems to be only a functional derangement of the abdominal vessels, for the attacks disappear with the removal of the irritating substance. In the treatment diuretin is the remedy *par excellence*, often producing prompt relief. This is probably due to its vaso-dilating influence. The allied substances, agurin and theocin, have a similar action. Strophanthus or digitalis, iodide of potash and the nitrites are also to be employed as circumstances indicate.

6. Minor, L. *Quinquaud's Phenomenon in Drinkers and Non-Drinkers, and in various Nervous Diseases.* (Continued.)

1. Under the name of pseudo-anemia, Strauss calls attention to a common condition in which the skin and often the mucous membranes are pale, but there is no true

anemia, the hemoglobin showing normal values. The cause is either decreased transparency of the skin, or local ischemia. Spasm of the peripheral arterioles is evidently present in lead poisoning and probably also in chronic nephritis. In a large group of functional nervous disorders the apparent anemia is probaby due to such a local contraction of the peripheral vessels, more or less permanent. Such patients frequently show other signs of instability of the vasomotor system, such as dermographia, flushing of the face, etc. The general condition should be treated, the use of iron being manifestly superfluous.

4. Experiences of various surgeons, especially Lennander, have apparently shown that the intestines and the other abdominal viscera are devoid of sensation. This work has been based on laparotomies on human beings under cocaine anesthesia. Kast and Meltzer, of New York, show in this article that the apparent anesthesia of these parts is entirely the effect, through the circulation, of the cocaine employed. Experiments on animals showed that the normal and, to a greater degree, the inflamed viscera are capable of sensation, while the injection of a small amount of cocaine promptly produces anesthesia.

1. That the dyspneic patient cannot lie comfortably in bed is usually explained by stating that in a sitting posture the accessory muscles of inspiration are mechanically better placed for work. However, many dyspneic patients are compelled only to assume a sitting position in order to sleep. Further, if this explanation were true, tracings made of the respiratory movements should indicate either an impeded inspiratory phase or the action of accessory muscles of inspiration. However, in many patients such is not the case. In individuals with pleural effusion whose dyspnea is particularly considered in this paper, tracings of the respiratory movements show, on the contrary, that expiration is impeded or there is evidence of the action of the accessory expiratory muscles. While awake the accessory expiratory muscles act and there is no dyspnea even in the recumbent posture. During sleep they cease to act and the patient is only able to get sufficient air in the sitting posture. In the recumbent posture the dome of the diaphragm extends farthest towards the head, while in the sitting posture it has its lowest position. In this latter position the pulmonary vital elasticity is at its maximum, and the stretched lung contracts forcibly to expel the air. In pleural effusions the lung is not compressed but the fluid prevents expansion of the lung, and so there results a deficient elasticity of the lung which is the cause of the dyspnea. This deficient elasticity is increased by the sitting posture because the diaphragm has a lower position and so expiration is favored.

2. Rubenstein reports a case of a boy of sixteen with marked anemia, and no absolute leucocytosis. However, there was a marked relative lymphocytosis, and autopsy showed a lymphoid marrow. He discusses the classification of such a case. He does not regard it as belonging to the lymphatic leukemias, but thinks it may be considered a case of myelogenous pseudoleukemia (one of Pappenheim's groups of pseudoleukemia). Of this he is not certain, so he suggests the name "anemia perniciosa myelopathica," as describing the condition.

3. This is a paper of over 100 pages in length with a bibliography of 136 titles. It presents a number of facts derived from a chemical and experimental study of the relation of bothriocephalus worms to anemia, and the attempt is made to apply these results in an explanation of the pathogenesis of pernicious anemia. Tallqvist finds that the bothriocephalus worms contain a lipoid substance which is strongly hemolytic, and a proteolytic enzyme. This hemolytic lipoid is not excreted by the worm but is freed with the disintegration or digestion of the segments of the worm. Fed to animals or injected subcutaneously, the lipoid produces a distinct anemia which has many of the characteristics of pernicious anemia. Bothriocephalus worms from cases which are anemic, in contradistinction to those from cases not anemic, show definite evidence of disintegration. During this disintegration, which is probably in part an autolytic process, the hemolytic lipoid is set free in the intestine of the host, and as it is not injured by the digestive ferments there present it may be absorbed and produce a hemolytic action with resultant anemia. Other flat worms do not contain this substance, but similar substances are found in several organs of man, notably the intestinal mucosa. In the digestive disturbances of anemia such substances may be absorbed and so lead to the production of a pernicious anemia. Similar hemolytic lipoids occur in malignant tumors and may explain the anemia so often associated. The proof of the presence of a hemolytic lipoid in the bothriocephalus worm is satisfactory as also is the evidence of disintegration of the worms from cases with anemia. However, the result of giving the substance to animals is not to the reviewer very closely analogous to the blood picture of pernicious anemia, and the attempted explanation of the pathogenesis of pernicious anemia on this basis seems somewhat far-fetched. [H. A. C.]

THERAPIE DER GEGENWART.

JUNE, 1907.

1. *ERB, W. *The Treatment of Neurasthenia.*
2. *SCHNÜTGEN. *Senator's Treatment for Gastric Ulcer.*
3. LENNÉ. *Further Observations on the Dietetic and Medicinal Treatment of Diabetes.*
4. *KLEMPERER, G. *The Treatment of Acute Articular Rheumatism.*
5. KUHN, P. *Buttermilk in Infant Feeding.*
6. *DAMMANN. *Emotional Disturbances and their Treatment.*

1. Erb, while admitting the important part played by the psyche in neurasthenia, does not believe in the psychic origin now so commonly invoked for this disease. The mental symptoms, according to him, are merely part of the general "irritable weakness" of the entire nervous system. In the treatment, rest, nourishing food and fresh air, with hydrotherapy form the essential features. Later on, the nervous system is to be strengthened by gradually increased active and passive exercises, sports of various kinds, hydrotherapy. In the use of the last, mild procedures are best. A change of climate either to the sea or the mountains is often beneficial, and withdrawal to a sanatorium is essential in severe cases. The Weir-Mitchell treatment has not proved valuable in his hands. Erb deplores the present neglect of drugs for physical methods of treatment, for he has often seen great benefit from medicine, especially iron and arsenic, alone or combined with nux vomica, quinine and other nerve tonics. Psychotherapy is quite in place to combat the various autosuggestions and to give the patient a firm conviction of an approaching cure.

2. Senator's diet for gastric ulcer stands midway between the low diet of Leube and the liberal one of Lenhartz. Its distinctive feature is the administration of gelatin in considerable quantities, the gelatin serving both as a food and as a hemostatic agent. In 50 patients treated in this way, Schnütgen reports (from Senator's clinic) a mortality of 4%. A favorable result, either improvement or "cure," was obtained in 94%; the average duration of treatment in these was only three weeks. In most of them the weight showed no decrease, or even a slight increase.

4. Theoretical considerations led Klemperer to the belief that the action of the salicylates in acute rheumatism is largely due to the production of hyperemia in the joints. To test this belief, he treated 68 cases with Bier's passive congestion exclusively. The results were good, and in cases of slight or medium severity a cure was usually obtained. The relief of pain was, as a rule, prompt and striking. However, out of 19 cases which proved refractory to congestion, 10 were promptly cured with salicylates, and in general the results with congestion

were somewhat inferior to those obtained with the drug. He believes that the salicylates produce hyperemia in the joints and exert also a slight bactericidal action, and advocates therefore a combination of the two methods.

6. After classifying the various diseased states of the emotions, and describing the general treatment, Dammann proceeds to a warm recommendation of bornyval for all excited states, especially hallucinations. It produces quiet without stupor or sleep, and has no after-effects. It was efficacious in nervous dyspepsia and in palpitation. Bornyval, or borneol-isovalerianic ester, combines the two active principles of valerian, the ethereal oil and valerianic acid, and is given in pearls in the dose of 0.25 gm. (4 gr.). [W. T.]

Correspondence.

AN APPEAL TO THE AMERICAN MEDICAL PROFESSION.

New York, July 30, 1907.

Mr. Editor: On May 8, the day following the meeting of the National Association for the Study and Prevention of Tuberculosis, there appeared in the *North American* of Philadelphia a most sensational article by Mr. Richard J. Beamish according to which, during the discussion of Dr. Flick's report on medication, I was reported to have advised the killing of dying consumptives quickly and painlessly by heavy doses of morphine and to have admitted that it was my daily practice to do so. It was furthermore said in this article that there had been a bitter debate and that the session adjourned in confusion. These false statements were copied by nearly all the newspapers in the United States, were cabled to Europe and made the rounds in the papers and magazines of England and the whole European continent. In spite of explanations and denials I had sent to the Associated Press, in spite of a strong letter written by Dr. George Dock, the presiding officer of the meeting, and sent to the leading medical journals of America giving the true version of my remarks, the false statement has continued to be published and republished and commented upon to the great detriment of the anti-tuberculosis crusade all over the world. For example, ignorant consumptives in St. Louis, who had read the sensational lie, refused the visit of the nurses sent to them by the Society for the Relief and Prevention of Tuberculosis. The *St. Louis Republic* which published this news item said, "Consumptives since they read that report apparently have a dread that the visit of the nurse may mean morphine to end their suffering." It became thus necessary to issue the following statement by order of Prof. Frank Billings, President of the National Association for the Study and Prevention of Tuberculosis:

"Various daily newspapers published on May 8 what purported to be a report of the remarks of Dr. S. A. Knopf, of New York, before the National Association for the Study and Prevention of Tuberculosis, in which he was made to say: 'It is my practice and your sacred duty when you see a dying consumptive before you to give the sufferer morphine in plenty that the end may come quickly and painlessly.'

"No statement was made by Dr. Knopf, but since, in spite of an immediate explicit denial by the doctor, a great many newspapers in this country and Europe continue to publish the false report as authentic news. Dr. Frank Billings, of Chicago, President of the National Association for the Study and Prevention of Tuberculosis, authorizes the following statement:

"'Quite apart from the false position in which the speaker was placed and the injury done him, the publication of such a piece of sensationalism cannot fail to have a very deleterious effect upon impressionable tuberculosis patients throughout the country and may keep others from seeking needed medical aid.'

"The following statement made by Prof. George Dock, of the University of Michigan, who presided at the meeting in which Dr. Knopf spoke, should preclude all further misunderstanding:

"'I heard clearly what Dr. Knopf said, I am sure that I know what he meant, and am sure that everybody in the room must have understood what he said. His words could not possibly be converted into the meaning given in the public press. It was perfectly clear that he meant to relieve patients in the last stages. Everybody knows this prolongs life while making it very much easier for the patient.'

"Livingston Farrand, *Executive Secretary.*"

I had hoped that this statement would put a stop to all further comments on and circulation of the sensational falsehood. I am free to confess that I have longed for the time when the lie would die out, for in spite of the loyalty manifested by my professional friends during these hours of trial, for which I beg them to accept my most heartfelt thanks, the ordeal had become almost unbearable.

It seems that such a lie dies hard and from time to time receives a new stimulus from the over-zealousness of some physician or layman. Thus, for example, through the courtesy of Dr. George H. Simmons, the editor of the *Journal of the American Medical Association*, I received a copy of the *Kansas City Journal* of last week, containing an editorial under the heading "Should Doctors Kill?" from which I quote the following:

"The question whether a physician is justified in shortening the life of a patient suffering from some incurable disease by administering anesthetics was given a fresh impetus recently by the declaration of Dr. S. A. Knopf before the tuberculosis congress in Washington advising that consumptives should be given heavy doses of morphine to hasten the end. To the credit of the profession it must be said that physicians generally repudiate the idea as atrocious and a violation of medical ethics. A Chicago physician, Dr. Charles Gilbert Davis, voiced this sentiment, saying: 'A physician who would make a statement of that sort should be taken out and hanged. The profession has not gotten so low that it must commit murder just because it has not yet discovered a cure for some disease. There is nothing incurable under the sun. Just because the cure has not been discovered, that does not mean that it never will.'"

In Dr. Dock's letter above referred to, as well as in the statement authorized by Dr. Frank Billings, the absolute falsehood of the respective newspaper report was clearly shown and it would seem that there was hardly an occasion for Dr. Davis to unburden his feelings for the benefit of the lay press.

Equally untrue was the report of the alleged "adjournment in confusion" and the "lively and bitter debate" which followed Dr. Flick's report, condemning the use of morphine and its compound. In refutation of this reflection made by Mr. Beamish on a body of scientific men composed of many of the leading American physicians, who have devoted their lives to the study and prevention of tuberculosis, permit me to publish, for the first time, an extract from a letter which was received recently by Dr. Joseph Walsh, the secretary of the section:

"I was present as secretary of the section at which you spoke and instead of the section breaking up in confusion as was stated in the newspapers, the section closed in the perfectly regular way, and your statement as generally understood by the medical men seemed to be generally agreed with."

I beg the Medical Press of the United States to copy this communication in the hope that it will help individual members of the profession to refute once for all the inconceivable proposition that any physician true to his calling could possibly propound such a doctrine as shortening the life of any patient entrusted to his care. To the individual member of the profession in this country and abroad I address a personal appeal to embrace every opportunity to disabuse any individual who may labor under the misapprehension that I or anybody else of the American profession recommended shortening the lives of consumptives or any others by the administration of chloroform, morphine or similar narcotics. I make this appeal not merely for my own sake but above all for the sake of truth and for the sake of consumptive sufferers in this and in other countries.

Truly yours,

S. A. Knopf, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JULY 27, 1907.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED JULY 24, 1907.

STONER, G. W., surgeon. Directed to proceed to El Paso, Tex., San Diego, Cal., and other ports on the Pacific coast and Canadian border, for special temporary duty, upon completion of which to rejoin his station at Ellis Island, N. Y. July 20, 1907.

MCMULLEN, JOHN, passed assistant surgeon. Granted extension leave of absence for seven days. July 18, 1907.

MCMULLEN, JOHN, passed assistant surgeon. Granted leave of absence for five days. July 24, 1907.

VON EZDORF, R. H., passed assistant surgeon. Granted leave of absence for two days. July 23, 1907.

KING, W. W., passed assistant surgeon. Directed to proceed from Tuckerton to Atlantic City and return, for special temporary duty. July 22, 1907.

STANSFIELD, H. A., passed assistant surgeon. Granted leave of absence for three months from July 12, 1907, with permission to go beyond the seas. July 18, 1907.

HOLT, J. M., passed assistant surgeon. Leave of absence granted Passed Assistant Surgeon Holt for two months from June 20, 1907, amended to be effective from July 7, 1907. July 18, 1907.

VOGEL, C. W., passed assistant surgeon. Relieved from duty in the Philippine Islands and directed to return to the States, reporting his arrival at San Francisco. July 20, 1907.

CREEL, R. H., assistant surgeon. Relieved from duty in the Philippine Islands and directed to return to the States, reporting his arrival at San Francisco. July 20, 1907.

LYALL, R., acting assistant surgeon. Granted leave of absence for three days from July 11, 1907, under paragraph 210, Service regulations.

OWEN, H., acting assistant surgeon. Leave of absence granted Acting-Assistant Surgeon Owen for thirty days from June 1, 1907, amended to be effective from August 1, 1907. July 18, 1907.

RODMAN, J. C., acting assistant surgeon. Granted leave of absence for fifteen days from July 1, 1907. July 17, 1907.

SEAVEY, L. T., acting assistant surgeon. Granted leave of absence for 21 days from August 15, 1907. July 19, 1907.

WELLS, R. S., acting assistant surgeon. Granted leave of absence for thirty days from June 1, 1907, account of sickness. July 18, 1907.

WELLS, R. S., acting assistant surgeon. Granted leave of absence for thirty days from July 1, 1907. July 17, 1907.

MORRIS, G. A., pharmacist. Granted leave of absence for fourteen days from August 10, 1907. July 22, 1907.

WATTERS, M. H., pharmacist. Granted leave of absence for 11 days from July 23, 1907. July 17, 1907.

HALL, L. P., pharmacist. Granted leave of absence for fourteen days from July 23, 1907. July 22, 1907.

APPOINTMENT.

DR. HARRY M. FRIEDMAN appointed as acting assistant surgeon for duty at Philadelphia, Pa., July 18, 1907.

DR. LOUIS A. THUNIG appointed acting assistant surgeon for duty at Stapleton, N. Y., declined appointment.

AMERICAN PUBLIC HEALTH ASSOCIATION.—The thirty-fifth annual meeting of the American Public Health Association, including the United States, the Dominion of Canada, the Republic of Mexico, and the Republic of Cuba, will be held at Atlantic City, N. J., from September 30 to October 4, inclusive.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING AUGUST 3, 1907.

L. W. BISHOP, passed assistant surgeon. Unexpired portion of leave revoked. Ordered to the "Missouri" August 1.

C. W. C. BUNKER, acting assistant surgeon. Ordered to the "Lancaster."

F. D. CHAPPELEAR, acting assistant surgeon. Resignation accepted to take effect July 31, 1907.

J. A. MURPHY, surgeon. Detached from the "Des Moines" and ordered to the "Dolphin."

H. M. TOLFREE, passed assistant surgeon. Detached from the "Dolphin" and ordered to the "Des Moines."

C. G. ALDERMAN, assistant surgeon. Ordered to the Naval Hospital, Puget Sound, Washington.

RECENT DEATH.

DR. EDGAR ELTINGE, retired, a physician formerly well known along the Hudson River, died at his residence in Kingston, N. Y., on July 27, at the age of seventy-nine years. He came of a medical family, dating back to colonial times, and was graduated from the College of Physicians and Surgeons, New York, in 1852. In 1884 he removed to Brooklyn, where he practised until three years ago, when he returned to his old home at Kingston on account of failing health.

Address.

THE PSYCHIC FACTOR IN DISEASE.*

BY DR. GEORGE CARROLL SMITH, BOSTON.

DURING the prevalence of the psychic epidemic, which amounts almost to a monomania in Boston, and is widespread over all New England, the writer has thought the attention of this society might be profitably focused for a brief hour upon this fad. I say *fad*, as it differs not in the least from similar delusions and makeshifts which have arisen, been exploited, had their nucleus of truth dissected out of them, and then dropped, under the searching light of scientific investigation. This epidemic differs in the following respects from that of ancient and medieval times: then the devotees and advocates were the ecclesiastics and people; now they are the various cults, some of the clergy, some of the people, and many of the physicians. There is nothing new in this idea, as it has existed from time immemorial; then why is it receiving so much attention? Is it not true that when no new thought comes to the front, old knowledge is raked over to see if there is not some idea in it which has not received sufficient attention? This factor is one which has not received sufficient emphasis — at least, so think the various cults, *et al.* — and as this method has biblical support it has become contagious. John Hunter said, "Everything new carries a greater weight and makes a deeper impression on a weak mind." It may be interesting here to note that all down through the ages, and especially in recent times, some of the greatest advocates of small and great problems, to establish their selfish sophistry and cunning, have wittingly misinterpreted that good Book which was designed to uplift and teach us a higher standard of living.

The powerful effect of the presence of the cheerful and optimistic family physician, speaking words of encouragement to his patient, has long been recognized not only by the doctor but by the by-standers as well, and, in numerous instances, at one interview in the doctor's office an issue of blood has been stanched. The palsied have walked, the deaf been made to hear, the dumb to speak, and the blind to see, but these, to the uninitiated, apparently miraculous cures, all save the first, took place among hysterics, hence the psychic treatment has reached its most conspicuous prominence and success in this effection. But in neurasthenia, hypochondria, melancholia and many other psychoses, as well as organic diseases to which there is almost always a neurasthenic element added, it has of late received renewed attention, and has in some hands been carried to unwarranted length, like electrotherapy, hydrotherapy or the appendix and ovariotomy craze, till now every case that is not clearly an organic heart, lung, stomach or kidney disease is at once declared to be psychasthenic and amenable to psychic treatment. The only reason for such an error is indolence, too great haste, or inability to make a correct diagnosis. When you reflect how difficult it often is to differentiate a general paralysis, a disseminated sclerosis or an exophthalmic goiter from a neurasthenia; a stomach neurosis from a carcinoma of that organ; a functional from an organic headache, etc., you can readily see how much easier it is to make snap diagnoses, and thereby save ourselves days, and perhaps weeks, of hard study to discover the latent disease.

The writer will endeavor in this paper to set forth his views upon the value of the psychic factor in the treatment of the so-called functional nervous diseases, where it is supposed, by some, to be our sovereign and only remedy. As it is generally conceded to be our most reliable method of treating hysteria, I shall not further allude to this disease, but devote my time chiefly to neurasthenia, briefly alluding to its congeners, hypochondria and melancholia. Every physician has to do with neurasthenia, as it complicates, to some extent, probably all organic affections in adults, and is often met with as an idiopathic functional disease, inherited or acquired. I am sure that we make the diagnosis of the idiopathic form much less often now than ten years ago, as long experience and study have improved our methods of diagnosing this affection. Sometimes long study of the case is necessary before the organic affection as the source of the diseased function is discovered. I will briefly cite the histories of a few cases seen during the past ten years. These are fairly typical of those which frequent the office of a doctor who has to do with chronic diseases, as well as the office of the general practitioner. The principal method of treatment used was psychotherapy, though in some instances other therapeutic methods were also used. Full details of these cases are for brevity omitted here, but later a routine outline of treatment follows.

CASE A. Female. Age thirty-six. Single. Music-teacher. Father had melancholia. Mother had tuberculosis and died when patient was very young. The child grew up in the care of her father, later was brought under the care of a hypochondriacal stepmother. After her father died she was obliged to support herself teaching music, which she found very taxing; she was compelled frequently to work far into the night, and very soon thereby found she was not sleeping well; then began to worry about her insomnia, till she got so she could not sleep at all. She then lost courage and began to cry much of the time. Her appetite waned, and the bowels became constipated. She was annoyed with palpitation, and her memory failed. After consulting several physicians, she was sent to a nervine asylum and treated for a number of months, then to the various cults, until she was thoroughly instructed in the worst of all methods used for the cure of such cases, viz., auto-suggestion. When she came to me she was continually repeating to herself, and audibly, "I am going to sleep to-night, I am going to sleep to-night," keeping her obsession constantly before her mind. There was motor inhibition — she would take two hours to dress herself if allowed. She was analyzing her sensations and accusing herself for her deplorable state. Physical examination showed no evidence of organic disease. This was clearly a case of beginning melancho-

* The Annual Address before the Rhode Island Medical Society, June 13, 1905.

lia. The treatment consisted in taking her away from all relatives, securing for her a good boarding place with a large, sunny room and a good nurse. Then the writer made out a program of mental and physical exercises for her which kept her busy all the time, with occasional resting periods. Her days were spent with music, art, French and swimming lessons, long walks, matinées, reading the standard periodicals. She was required to tell what she read from day to day. No one was allowed to discuss her health with her. She was given better subjects for thought, and for a few nights a mild soporific, then a placebo for awhile, finally nothing. After four months she was cured. The treatment was essentially re-education; the substitution of good ideas for bad, total change of environment, good air, sunlight, and, most important of all, occupation, but the greatest care was used to make her work pleasant, and to have a period of seriousness followed by one of fun. One year has passed without recurrence.

CASE B. Civil engineer. Age twenty-six. Patient first came to me when he was in college, with all the classical stigmata of neurasthenia inherited from and further nurtured by a hysterical mother. He was very thin and underfed from fear of eating. By a slow process of re-education he has gotten free of his symptoms after *seven years* of persistent mental training; but now, when he has an acute attack of indigestion, the gastro-intestinal symptoms last longer on account of his heritage. He is now filling a very prominent position in a neighboring state, and I referred him to an eminent doctor in New York if needed at any time. I was quite surprised, six months ago, to receive a letter from that physician, saying that my patient had called upon him and he had found tuberculosis in the left apex, and had advised his coming on to see me, which he did several days later, when his râles had disappeared and he was quite well again. Attention is called to this case for three reasons:

(1) It was one of the most obstinate of my cases which yielded perfectly to psychic treatment.

(2) The long time required for training.

(3) To call attention to the fact that the best diagnosticians may mistake functional nervous diseases for organic.

CASE C. Clergyman. Age thirty-one. Patient's father, mother and two brothers were neurasthenic. A third brother was successfully treated by me for melancholia. Patient had a nervous shock at fourteen, which affected his eyes. The eye muscles were cut several times. At twenty-one, had nervous prostration, melancholia with suicidal tendency. Has suffered since with neuralgia of various parts of the body, but quite often beginning in the pit of the stomach. Ten years ago the pain was accompanied with chills, fever, vomiting and jaundice. He now has fatigueability, anorexia, indigestion, post-cervical ache, numbness and formication of the limbs. His nerve reactions are much quicker than normal, and he is very introspective. His gall-bladder region is exceedingly sensitive. This case illustrates the not uncommon occurrence of an organic disease in a neurasthenic patient. This patient bought an abandoned farm, worked on it for six months and regained his health.

CASE D. Male. Age nineteen. Has always had headaches. Seven years ago was properly refracted, and the headaches became less frequent, till now they recur once a month, and are of the migrainous type. Is easily excited, and has emotional fatigue. Two years and a half ago fell from a hammock and got a diarrhœa which has persisted at intervals ever since, four or five movements daily. Any excitement, like getting ready for a party, or to go to the theater, was enough to produce it. There was no mucous or blood in the stools, no tenesmus or griping. Had lost confidence in his bowels and rectal sphincter, and must always plan to relieve the former before any public undertaking. His father is nervous and has this form of diarrhea. Now the fact that this boy early heard his father complain so much of this particular symptom, coupled with his fall, was quite enough to determine the same symptom in himself. Drug treatment, directed by a very competent physician for two years, had failed. This patient was trained to control his sphincter and to regulate his daily movement after breakfast by the clock, and the force of correct habit soon asserted itself. He was under treatment about two months, and one year later reported himself well.

CASE E. Male. An artist. Age twenty-seven. Family history negative. Patient well till three years ago. Has since suffered with dyspepsia. His meals are simple, but he bolts his food. Has constipation or diarrhea most of the time. Has had at times a good deal of gas in the stomach and bowels. The past six months has been blue. Worries a good deal; is tired all the time, and occasionally sweats on emotion. Has been told to rest, and tried it without benefit. He has lost confidence in himself to do good work, and recently gave up an order to paint a portrait because he feared he would fail if he attempted it. Two psychic treatments sufficed for the cure.

Occasionally it has been found necessary to isolate patients, but rarely to give them long periods of rest according to the plan established by our highly-respected pioneer, Dr. S. Weir Mitchell. An exact knowledge of the patient's life, including his environment, habits and mental resources, will alone determine the question of isolation. The question of absolute rest depends for its solution more upon his previous occupation and his temperament. If his life has been particularly strenuous in a mental or physical sense, he should have a short period at least of absolute rest in bed, with a milk diet which taxes the digestion least, and favors sleep, which is the greatest restorative. Most neurasthenics and practically all hypochondriacs and melancholiacs do best when frequently diverted, and kept busily occupied in varied but pleasing and interesting as well as serious pursuits.

For the purpose of study, the writer has taken at random a hundred neurasthenic cases from his card histories, and divided them into two great classes: (1) Those born with an inherited predisposition — children of tubercular, alcoholic, syphilitic and nervous parents especially — are predisposed to the affection, as the digestion of such patients is readily impaired, and their delicate nervous protoplasm suffers still more from faulty metabolism. Such patients are very susceptible to indigestion, mental or physical shock, fright and emotional disturbances, and from their number furnish us with our best types of traumatic neurasthenia. A large number of our nervous dyspeptics belong to this class, and by carefully watching their numerous bodily sensations the latter soon become pathological, and the habit of auto-suggestion is established and erelong such patients may become hypochondriacal.

(2) Those whose heritage is good, but who acquired the affection by bad environment, improper training in youth at home and in school; persons who worry for fear of not making both ends meet; and those who have habit spasm.

Of the 100 cases analyzed, 43 were clearly hereditary, 57 acquired. Forty-eight co-existed with faulty metabolism. It was interesting to note that low metabolism was the stigma in the majority of the hereditary cases, and in some of the acquired class, so that it is often difficult to assign some patients to either class, while in some of the acquired cases a severe disease of the gastro-intestinal tract in childhood could be elicited, which, of course, gave rise to the faulty metabolism. The frequency of tuberculosis in their parents clearly shows the necessity of stamping out this far-reaching scourge as a means of prophylaxis in diseases of the nervous system, as well as for other numerous well-known reasons.

Of the 48 metabolism cases, 30 were of gastro-intestinal origin; 7 followed severe illness; 9 were traumatic; 6 were brought on by shock or mental strain or worry; 2 followed the use of alcohol; 1 followed continual absorption of toxine from decayed teeth; 1 co-existed with floating kidney; 2 were due to the use of a stomach tube.

No cases in this series were found due to overwork, excessive use of drugs, eyestrain, nasal obstruction, middle ear disease, or disturbed or deficient sleep, unless we except Case A, in which insomnia was the ultimate cause of the slump.

The method adopted by the writer in the treatment of cases is essentially the same as that set forth by Professor Oppenheim in the "Psychotherapeutische Briefe" published last year, with this exception, that I do not carry this out by correspondence, as I have found office instruction served the purpose, and to save your time and patience I will briefly describe the treatment of a neurasthenic case of the common type, which comes to our office daily, which will show sufficiently the method involved in the psychic treatment of the functional diseases which are supposed to be amenable to cure by this method. The most conspicuous symptoms complained of by such a patient are fatigue, palpitation, constipation, diarrhea, insomnia, headache, loss of memory, worry, phobias, irritability. It is necessary to detain you now with only the most prominent of these. The patient is told that such symptoms are experienced at times by all human beings; the only difference between his sufferings and that of the rest of mankind is that his symptoms have become accentuated by giving them more attention, until they now last longer, and are more intense, and to eradicate them entirely it is necessary that he should understand their origin and nature, then he can readily see how they are to be avoided and eliminated. He cannot be too often reminded of the wisdom of the saying, "As a man thinketh in his heart, so is he." Re-education is our watchword. It is explained to him that the more nervous a man is, the more readily he reacts to irritations from within and without. Let us first study fatigue, as it is one of the most common symptoms.

Fatigue is a state wherein, owing to over-activity of an organ, the nutrition suffers and halts. Under the Edinger law, an old pathological principle has recently been revived, to wit, increased function leads first to increased growth, but when carried to excess, particularly if spasmodic and irregular, it terminates in atrophy and degeneraton of the structures concerned, and is followed, *pari passu*, with an overgrowth of the surrounding structures.

Wells says, "Fatigue seems to be due to an intoxication with products of the excessive metabolic activity, and part of the symptoms, at least, seem to be due to acid intoxication. Among the metabolic products of muscular activity are known to be creatin, creatinin, sarcolactic acid and carbon dioxide. When the activity of a muscle is violent or prolonged, the sarcolactic acid and CO_2 accumulate, being formed faster than they can be removed." Halleck says fatigue shrinks the nucleus of a cell 50%. It required a long time for us to learn that we could not rest our brains by going into a stiff game of golf, tennis or polo; but physicians to-day who think and observe, know that the same brain innervates the muscles as the special senses and intellectual faculties. They also know that the sympathetic nervous system participates in the same hardships as the cerebro-spinal system. Indeed, upon the intregity of the former depends the kind and amount of work of the latter. Note the lessened activity of the arterio-sclerotic, and his ready fatigue.

Now, the fatigue of the neurotic may be physical, mental or emotional. The first two rarely occur, and the former is so generally harmless, and, indeed, so beneficial in early life, it may here be ignored. Charcot said a child under fifteen, when fatigued, stops working, while an adult forces his brain to continue. Again, an adult has grave responsibilities, which often weigh so heavily in consciousness that he cannot suppress them with other thoughts, and the emotional fatigue becomes superimposed. Of course, when mental fatigue is accompanied with worry, only harm can result. Every observer will agree with DuBois that emotional fatigue is psychical when due to worry, unpleasurable sensations, anger, passion or fear. Here unquestionably the fatigue is due to several factors, among which is the perverse function of the vaso-motor system regulating the blood supply to the nerve centers; but by far the most important factor is the habit of auto-suggestion. These patients are tired from habit before they start out to do anything. This, of course, is purely psychical, and their mental representations must be clearly explained to them, as due, perhaps, in the first instance, to fear, anger, worry, etc., but later to an auto-suggestion. This establishes the habit. The writer finds the fatigue habit, like most other habits, dates back to childhood, when everything is learned by repetition. Ribot says, fatigue in every shape is fatal to memory. The impressions received under such conditions are not fixed, and the reproduction of them is very laborious and often impossible. When the normal conditions are restored, memory comes back.

The habit of auto-suggestion must be broken. New thoughts must be suggested. An altruistic

philosophy will appeal to some, while stoicism may be accepted by others. At all events, such patients require a good deal of suggestion, persuasion and encouragement. Professor James says the human individual lives usually far within his limits. He possesses powers which he fails to use. He energizes below his maximum, and behaves below his optimum. His life is contracted like the field of vision of an hysterical subject. The existence of reservoirs of energy that habitually are not tapped is most familiar to us in the phenomenon of "second wind." Ordinarily we stop when we reach the first effective layer of fatigue. We have walked or worked enough to desist, but if an unusual necessity forces us on, the fatigue gets worse up to a certain critical point, when gradually, or suddenly, it passes off, and we are fresher than before. We have tapped a level of new energy. This may go on indefinitely. Professor James quotes the Yoga exercises for increasing our will. The power that we do not use up completely can be brought, more and more, into use by faith. Faith is like the manometer of the will, registering its pressure.

Palpitation is next explained to our patient. He is told how it may arise. Numerous causes are cited, like over-eating, fermentation, shock, emotion, fright, strong tea or coffee, smoking, intestinal parasites, ovarian irritation, etc. Then the specific cause of *his* palpitation is sought after and found. The method of its intensification and prolongation is analyzed by showing him how the attack first arrested his attention and fixed his observation, so that he became introspective and repeatedly began to listen for the pulsation, increasing it thereby, and prolonging its duration, as he developed the acuteness of his hearing. His attention is called to the fact that when he changes his position so that he cannot hear it or his attention is diverted, he is no longer conscious of the palpitation, and to enforce this he is told that when the writer examined him with his attention concentrated upon his heart, it beat very forcibly and rapidly, but later, when his mind was fixed upon some other subject, the pulsation became normal. He is next shown how he may invoke palpitation by running up stairs, or going through some hard stunts in the office, and yet, as soon as he rests, or is diverted for a few minutes, he is unconscious of the beating. On the other hand, if he persists in studying it, he becomes more sensitive till he can, by force of will, set up palpitation, and can even become conscious of the pulsations of the arteries of the body. By carrying this idea a little farther, slight irregularities of the pulse are readily explained. He is shown how these pulsations, after a time, may become painful, on the ground that any disagreeable sensation long continued is painful. The cause of the first attack of indigestion is then sought, and most often found due to constipation, over-eating or bloating, which is readily explained as arising from faulty habits. The frequency of the repetition of the faulty habit prolongs the duration of each attack until it becomes quite permanent. Now, a healthy man should not, under ordinary circumstances, be conscious of the processes of his own circulation, digestion, peristalsis, etc., but by introspection this *is* possible, and gives rise to painful sensations. Rarely does the writer rely upon psychic treatment alone to relieve palpitation, because there are many other curative agents which give immediate relief, while the former requires long training. Among these agents is an ice-bag over the pericardium, which acts by virtue of its temperature, weight and suggestion. A pelotti, a kind of truss, suggested by Dr. Crofton, acts well also, emphasizing more the pressure and suggestion. Reflex stimulation of the vagus by deep breathing, or by smelling salts, often gives quick relief. The bromides are our best drugs, and the reader prefers the ammonium salt, as it does not depress, except in such cases as require depression. It is quite easy to see how a person lacking in nerve force may eat some indigestible food and suffer slight sensations of discomfort, which cause, at first, watchfulness, which soon leads to fear and worry to aggravate his distress, till he has really inhibitory impulses from his brain, causing motor insufficiency; and if maintained for a long time may cause secretory disturbances. Now the writer does not believe this is frequently the case, but does happen occasionally, even in the neurasthenic, and much oftener in the hysteric and melancholic. Whenever stasis occurs, of course fermentation takes place, which further intensifies the painful sensations, and, worse than all else, intensifies the fear and worriment. As *fear* and *worry* are really materially involved in all the other symptoms discussed in this paper, the writer is reluctantly compelled, for brevity's sake, to give them only casual notice. The best way of overcoming simple functional constipation and diarrhea is education of the patient.

Insomnia arises from a great variety of causes; among the most important of which are headache, reflexes from the heart or abdomen, or vaso-motor insufficiencies, which lead to cerebral flushing. These sudden irritations of the cerebrospinal centers quite suffice to cause restlessness enough to prevent the patient from falling asleep, or make him sleep so lightly that a little extra irritation from within or without awakens him often. Here, too, we see the force of habit in the most eclatant form. Active business men as well as society people, especially those of emotional temperament, carry the thoughts of the day to bed with them, and go on thinking about them well into the night. This habit must be stopped by happily diverting their evening thoughts into other channels which are full of fun and pleasure. Games, theaters, places of amusement, long promenades in company with cheerful and bright companions, singing or reading aloud usually serve this purpose best. In other cases, a warm bath or light calisthenics, in which the patient can use his brain as well as muscles, may be necessary. To this end, deep breathing exercises, which create a little muscular fatigue while fixing the attention, act well.

Another large class suffers from insomnia be-

cause of extremely sensitive peripheral reflexes from the skin as well as internal organs. These reflexes must be sought, found and corrected. Hydrotherapy is our best remedy with this class. The diet should be carefully regulated. Bromide, in frequent doses through the day, may be necessary to break up the habit.

The treatment of headache depends also upon its etiology. Often it is secondary to insomnia, gastro-intestinal reflexes or palpitations, and when the patient is relieved of such causes his headache disappears. Quite often, however, in the writer's cases, was toxemia the cause of the headache, especially that occurring early in the morning and disappearing after breakfast. The common sources of this toxemia are sometimes a pyorrhea alveolaris, a fermentation and putrefaction of the gastro-intestinal contents, coprostasis, insufficiency of the liver and kidneys, latent suppurative foci, perverse metabolism, gallstones, bladder diseases, etc. Not infrequently it is difficult to discover the toxic origin of the headache, and repeated examinations must be made, and the most careful eliminative inductive study instituted before an accurate diagnosis can be reached.

The subjects of auto-toxemia and faulty metabolism are of such pre-eminent importance in this study I am sure you will readily go with me into the most recent authoritative literature pertaining to this subject. Auto-intoxication, or intestinal infectious toxemia, is studied by watching the changes which the carbohydrate food and the proteid undergo in their passage through the intestine. The fermentation of the carbohydrates occurs in the lower ilium and colon; the putrefaction of the proteid takes place in the large intestine. Putrefaction, except in pathological conditions, never occurs above the ilio-cecal valve. In the cecum and ascending colon, putrefaction and fermentation are active together, hence bacteria are found most abundant in the cecum. Strasburg states that one-third of the weight of normal solid feces may consist of bacteria, and this proportion is greatly increased in diarrheas and lessened in constipation. Herter found that administration of indol to healthy men causes frontal headache, irritability, insomnia, and confusion; and a long continuance of the absorption of indol causes a strong reaction for indican in the urine and is sufficient to cause neurasthenic symptoms. A. E. Wright says, regarding the bacteriology of the intestinal canal, the bacillus coli and the streptococci allied to the pneumococci are the chief bacteria found in the colon in health and these are enormously increased in morbid conditions of the colon, and may spread to the small intestine, stomach and gall bladder. It is probable that the bacterium coli is the cause of the toxemia in neurasthenia. The products of fermentation — gases, fatty acids and lactic acid — are mostly absorbed by the intestinal wall. The gases are excreted again in the expired air. The fatty acids are either oxidized and expired, or eliminated unchanged in the urine. The fermentative products not absorbed go off as flatus. Putrefaction of protein produces ammonia, sulphuretted hydrogen and other gases, CO_2 and H and a number of bodies — aromatic oxyacids, phenol, skatol, indol, etc. These are absorbed by the intestinal wall, the gases are expired. The other substances are excreted in the urine as compounds of sulpho-glycuronic acid, or go off in the feces. Ortweiler and Müller have shown that the amount of indican in the urine varies with the length of time the feces remain in the colon; with the activity of the peristalsis; and, most of all, with the site of the putrefaction. If protein putrefaction extends up into the small intestine, the urine indican is much increased. Müller says in Kongress für innerer Medicin that many infectious diarrheas owe their origin to poisons taken in, already formed in the food; such poisons occur in meat, milk and cheese. Other cases may be due to the excretion, through the intestinal mucosa, of poisons formed in diseased tissue elsewhere, sepsis, pneumonia, uremia, etc. Such cases come under the head of infectious toxemia. Nothnagel took the same view while the French, English and American schools use the term auto-intoxication for this condition. You are all familiar with the usual symptoms of this toxemia — obstinate constipation, headache, giddiness, neuralgia, ill-humor, and so on. Gastric vertigo and tetany are explained by the French as auto-toxic, while F. Müller and other German scientists regard them due to a nervous reflex. The latter trace epilepsy, eclampsia and visceral psychoses to acetonemia, Albee and others to auto-intoxication. With either conception of the etiology of these toxemias, no one would for a moment expect to accomplish much in their treatment with psychotherapy. Improvement is only brought about by using every means at our disposal: (1) Elimination by all the emunctories of the body, but especially by the bowels and kidneys. (2) Hydrotherapy. (3) By adapting the food to the competency of the digestive organs. (4) Climatology — with special reference to sunlight, winds, etc. (5) Mental and physical exercises; in short, everything which will induce a better metabolism must be resorted to. Von Noorden says: " Mental action excites greater bodily activity by raising the potential energy of the nervous system." The nervous energy acts by setting free the muscular system. Psychical influence plays quite an important part in raising the potential energy of the nervous system, and in this manner arouses activity. Light and sunshine give rise to *muscular activity*, improve bodily metabolism, strengthen the action of the heart and lungs and favor the circulation of the tissue fluids; hence, light and sunshine must be regarded as very potent therapeutic remedies. In the same manner, Wolpert showed that cool winds act favorably by increasing bodily movements. These are, however, indirect methods of influencing favorably metabolism. Speck " found no alteration in gaseous exchange nor in heat formation when intense mental work was engaged in for a short period, and Atwater arrived at the same results after longer periods of three days." The standard taken for comparison was

the metabolism of an indivdiual in complete relaxation. Oppenheim found the same true for the metabolism of protein, and the latter, with Speck, affirms the same with regard to the excretion of nitrogen and urea during active mental work. Such scientific results should at least do away with formerly entertained notions concerning brain work.

To sum up, then, the requirements of the physician to practise psychotherapy successfully are:

(1) A strong personality.

"The mind casts a shadow just like the body."

"The mind of the doctor, in itself and in its manifestations, in conduct, manner, face, dress, ways, must, *ipso facto*, affect his patient for good or ill," says Schofield.

But we should remember, when striving to develop a strong and attractive personality, that the human side is by far the most important, or the saying of the witty Frenchman will apply to us, "He was born a man; he died a doctor."

(2) Thorough knowledge of the patient. The doctor must know his patient thoroughly, as Dr. Collins suggests, and, above all, should he know his mental habits and be able to put himself in his patient's moods, that he may make proper and helpful suggestions; otherwise he may antagonize his patient, or excite worse fears than he already has. We cannot regale a patient suffering with exophthalmic goiter by reciting Shakespeare, or relieve a melancholic clergyman by praying with him.

(3) Considerable knowledge of psychology is, then, necessary. Suggestions should always be made by the doctor, instead of the nurse, attendant or masseuse, who have had no training in this subject. And just here I would insist on exercising the greatest care in the selection of such attendants, as I am sorry to say the most of them have not yet learned that "silence is golden." The physician should have free hand in the selection of his consultants in these cases, as many of our best consultants on other affections, for want of knowledge of neurology, lack of interest in or patience with the functional neurotics, are not only incompetent, but do positive harm by incorrect diagnoses and bad suggestions. No better proof of this is needed than the obsessions of our daily patients, which have been fixed by former reputable physicians, under whose care they have at some time been. On the other hand, a good consultant will enlighten us, give us new zeal, and inspire our patient with a helpful faith. We are all, when in perfect health, or suffering from organic or functional disease, very amenable to suggestion.

The writer quite agrees with Dercum that "direct suggestion is most useful in hysteria, less valuable in neurasthenia, and least of all in hypochondria." Indirect suggestion is that generally employed in neurasthenia, but no general rule can be laid down which will apply to all cases. It should be remembered, however, that suggestive therapeutics is a synonym for psychotherapeutics, and it is the most powerful curative agent we possess in the class of cases alluded to, but it is a two-edged sword, hence upon your skill and tact in its use will depend your success. The assurance with which the physician says the patient will improve increases his faith. Unless your patient has faith in you, he should be encouraged, in a humane spirit, to put himself under another physician's care, since no doctor can successfully treat *all* his nervous patients.

(4) Broad, scientific medical training.

In the light of the foregoing, I am sure you will agree with me that in no other specialty is such a broad, scientific medical training necessary. As in every other method of treatment, a correct diagnosis must first be made, otherwise we may lose valuable time, and, perhaps, life, by treating a pernicious anemia, a latent tuberculosis, an interstitial nephritis, psychotherapeutically. A scientific, practical physician will use *every other therapeutic method at his disposal*, as well as psychotherapy. He will employ dietetics, hydrotherapy, electrotherapy, pharmacotherapy, isolation, rest, exercise, sunlight, pure air, winds, proper food and clothing, knowing that several remedial agents will often bring relief or cure more quickly than one alone.

Prophylaxis must always be kept in mind, as such a large percentage of neurotics trace the origin of their affection to their childhood. Parents should be educated along physiological and psychological lines. They should be taught to look after the environment and school life of their children as nearly all fixed habits are formed in early life by the repetition of simple acts; hence we see our purest examples of spasmodic tic in children who have learned them through mimicry. Dietetic and mental hygiene in youth will do much toward preventing mental slumps later in life. Barker has found that patients past middle life do not yield to psychotherapy so well as those between twenty and forty; first, because they are so opinionated; second, most people past forty already have organic disease. My experience confirms this view as applied to the functional neuroses, and I would like to add that the chief value of the psychic factor is in the care of organic diseases, as the functional affections are fast disappearing under the light of better diagnoses. I would emphasize, however, my belief that in *recent years* the eminent rôle played by psychotherapy is *wholly unjustifiable and misleading*.

The great mistake being made at the present time is in trying to incorporate the science of medicine with theology. The two sciences are just as distinct as law and medicine. The fundamental principles of right and wrong may be identical, but the deductive processes by which the sciences are built up are so different that the students of one know essentially nothing of the other. We of the medical profession, to-day, need the Bible to teach us morals, to make us humane, but not to teach us law or medicine. No man without a conscience founded on the highest sense of moral ethics is wanted in the medical profession. Let honesty prevail, then, from principle rather than policy. Let thorough earnest laboratory research, coupled with care-

ful clinical study, not only of disease, but of humanity, continue in the future, as in the past, to actuate our profession. Then our brilliant record of progress in the last half century will pale before the still greater achievements of the century upon which we have but just entered.

THE BLOOD PRESSURE AS A GUIDE IN THE TREATMENT OF HEMOPTYSIS.*

BY EDWARD O. OTIS, M.D., BOSTON.

Visiting Physician at the Massachusetts State Sanatorium.

In the treatment of no symptom or complication of disease does that old aphorism of Hippocrates, "Experience is fallacious and judgment difficult," seem so true as in that of hemoptysis. Consider the differing opinions and experience of so many and keen observers from almost time immemorial to the present day; and still the treatment continues to be largely empirical. More particularly does this Hippocratic maxim seem true with regard to the use of ergot. Were such experienced clinicians and careful observers as Wilson Fox, West, Ransom, Cornet, and many others entirely deceived in their opinion and experience as to the value of ergot, or, as I am inclined to believe, did they not meet with apparent success sufficient to warrant their conclusions? Still, we must admit, as Fowler observes, that "in the great majority of cases of hemoptysis with a limited area of disease, the bleeding ceases spontaneously, provided the patient keeps absolutely quiet and observes the ordinary rules which prudence suggests," and, therefore, he continues, "it is obvious that under such circumstances any remedy which is given sufficiently often may obtain an undeserved reputation." And this may be as true of the nitrites, now a popular remedy, through the writings of Hare and others, as of ergot.

Hemoptysis is a symptom dependent upon many and varying conditions, conditions difficult, if not impossible, to determine in every case. We have the underlying cause, the local process, its activity, degree of softening, and the state of the blood vessels in the diseased area; we have the individual diathesis; we have the various exciting causes, the activity of the circulation or blood pressure, the state of the nervous system, exercise, metabolic activity, mental excitement, causes dependent upon the sexual system, cough, and, doubtless, many others. It is, therefore, obviously, extremely difficult to judge of the effect of any remedy or to administer it with precision, and, indeed, one despairs of ever arriving at any great accuracy in the treatment of this symptom and congratulates himself that, in so many cases, it ceases without treatment.

In what I have to say in these notes regarding hemoptysis, I do not include those cases of overwhelming and fatal hemorrhages, obviously due to the rupture of an aneurysm in a pulmonary vein, for no treatment in such catastrophes is of avail. I refer rather to the less severe cases occurring generally in the earlier stages of the disease and particularly to those which are recurrent or persistent.

Of late years, since the sphygmomanometer has come into use, the blood pressure as a causative factor in hemoptysis has been receiving renewed attention, although the older writers were not unmindful of this factor, as witness Flint, who says: "There is a marked difference in different cases with regard to the activity of the circulation, or, to speak more definitely, of the heart as represented by the character of the pulse." And Wilson Fox, who says, in referring to the use of ergotine: "It is a remedy which should be used in severe and intractable cases attended by a *soft* and *rapid* pulse," or, as we should say now, a low blood pressure.

Lawrason Brown read last year a very suggestive paper before the National Association for Study and Prevention of Tuberculosis upon the treatment of hemoptysis by the nitrites, based on observations of blood pressure; and Hare, of Australia, in various papers speaks enthusiastically of his success and that of others with nitrite of amyl in hemoptysis, based on the well-known action of this drug in producing a marked and rapid fall of blood pressure.

Hare † evidently assumes that every case of hemoptysis results from a comparative increased blood pressure and reports sixty cases from his own practice and that of others in which nitrite of amyl was used, and in which, with one partial exception, "the bleeding ceased or became re-

* Read at the meeting of the American Climatological Association, Washington, May 7, 1907.

† The British Journal of Tuberculosis, Vol. 1, No. 1, p. 55.

duced to a mere staining of the sputa immediately — that is, within a minute or so."

Inspired by these reports, as well as actuated by the desire to see if we could obtain further light upon the value or worthlessness of ergot in hemoptysis we began, about a year ago, to take the blood pressure in cases of hemoptysis occurring at the sanatorium, and, so far as we were able, guide our treatment by the indication thus given.

A Janeway sphygmomanometer, with the wide cuff, was employed and the nurses instructed in its use.

As hemoptysis is such an alarming symptom and so often occurs without warning, our first effort was to stop the hemorrhage, and our blood pressure observations had, necessarily, to be more or less of a secondary matter. Furthermore the majority of cases occurred in the night or early morning, when the physician was not on hand to make or verify the observations or direct the treatment, so that the nurse at the inception of the hemorrhage followed the routine treatment, consisting of cracked ice, a small or large dose of morphia and atropine hypodermically, according to the urgency of the case, and the inhalation of nitrate of amyl, if it seemed to be indicated. Occasionally, only cracked ice was given as a placebo.

I have, however, eighteen cases, mostly recurrent, to report, in which the blood tension was taken at or as soon as possible after the hemorrhage began. In most of them, besides the immediate routine treatment above mentioned, if that did not suffice, either the nitrites or ergot were employed, depending upon the blood pressure; if this was comparatively high, the former was given, and if low the latter, whose physiological action, as we know, is an increase of blood pressure in the aortic system by a contraction of the arterioles through stimulation of the vasomotor nerves (Babcock, Kobert) and also, as Jacobi (quoted by Cushny) has shown, by direct action on the muscular wall of the vessels.

Hence, if ergot is of value, it would seem to be obviously so in a condition of lowered blood pressure when the hemorrhage might be considered to be more of a passive than an active one; and Babcock ("Diseases of the Lungs"), though he decries the use of this drug, very logically says: "If hemoptysis were in every instance due to relaxation and transudation, ergot might do good." Our reasoning was that if the blood pressure will enable us to determine these exceptional cases in which the hemoptysis is due to relaxation, why may not ergot be a rational indication in continued and recurrent hemorrhage — for the action of ergot is too slow to produce immediate results — and may not the success attributed to its use have occurred in just such cases? In a number of cases, whatever the blood pressure, if the indicated drug (by the blood pressure) appeared to exercise no beneficial influence upon the hemorrhage, we tried that contra-indicated by the blood pressure and apparently sometimes with success.

In order to obtain what might be considered a standard of blood pressure among tuberculous individuals, it was taken in 320 cases in the sanatorium, and the average was found to be 124 mm., Hg. Of the men it was 128 and of the women 115. Of 42 male patients the average blood pressure was 126, the highest 140, and the lowest 100. Of 43 female patients the average was 120, the highest 132, and the lowest 98. We, therefore, considered 126 mm. as the average blood pressure in tuberculous persons.

It must be remembered that the ordinary method we have of measuring the arterial blood pressure is not of precise accuracy, and apparently slight influences, such as mental excitement, physical exertion, the process of digestion, etc., cause it to vary considerably within certain limits. In the cases herewith given, for example, this variation is seen to be quite extensive. It is well to take the pressure several times at intervals in order to obtain a fair approximation of the real tension.

In the eighteen cases of hemoptysis, with the blood pressure herewith given, it is seen that the majority of them are below our average blood tension — some of them markedly so. The highest was 145 and the lowest 74; the average was from 109 to 119.

In nearly all the cases, when any treatment was considered necessary, the routine one, before mentioned, was at first employed, namely, ice, morphia combined with atropine, or heroin, with or without nitrite of amyl, depending upon the rapidity and amount of the hemorrhage. On the recurrence or persistence of the bleeding, either ergot or the nitrites, in the form of nitrite of sodium or nitroglycerin, were then tried, depending upon the blood pressure. If one of these two drugs did not appear to produce results, given according to the indication of the blood pressure, the other was exhibited whatever the blood tension might be. Both in certain cases seemed apparently effective, and both in others ineffective.

The detailed histories and charts of individual cases illustrate the varying treatment based upon the blood pressure, and the apparent results of the same. They also show how extremely difficult it is to estimate the effect of any one drug given for a complex symptom caused by so many and varying conditions, and they would also seem to indicate that the blood pressure, though of value as a guide, is by no means an infallible one; a conclusion which we should expect, for the tension is only one of the factors in this complex symptom.

These observations are, I am aware, imperfect and conflicting; they show nothing clearly. I trust, however, that they may throw some light upon the subject and indicate a little more definitely the path of treatment. I would suggest that the blood pressure should be taken of every sanatorium patient, since it can so readily be done in an institution as a part of the routine. We would then have this observation already at hand, as a guide, whenever a hemorrhage did

CASES OF HEMOPTYSIS AT THE MASSACHUSETTS STATE SANATORIUM.

	TIME OF OCCURRENCE.	AMOUNT.	BLOOD PRESSURE.	TREATMENT.	RESULTS.
A	3 A.M.	℥iii later. ℥ii or ℥iii.	110mm. Hg.	No treatment at first. Calcium lactate subsequently.	First hemorrhage ceased. Small hemorrhage later and streaked sputum.
B	Night.	℥ii first day. ℥iii second day.	116 at first; later period 102 to 122.	No treatment.	Two small hemorrhages only on two successive days.
C	2.15 A.M.	℥iiiss.	104 at 10 A.M.; 112 at 6.15 P.M. on the next day.	Heroin and cracked ice.	Apparently ceased.
D	About 4 P. M. and in night.	℥i twice, two successive days and clots.	100 to 120.	Morphia or heroin during hemorrhage; ergot later.	Clots continued about twelve days; *no increase* of blood pressure under ergot.
E	Not given.	℥ss to ℥v on two successive days.	112 to 154.	Nitrites, calcium chloride, codeia.	Apparently ceased on second day.
F	Early morning and during day.	From Nov. 25 to Dec. 11, ℥xliii.	94.	Morphia, atropine, nitrites, ergot for several days.	Ergot appeared to stop the hemorrhage.
G	9 A.M. 8.45 P.M.	℥iii ℥i.	126 following day; in 6 days later, 88.	Morphia, atropine, heroin, ice, mag. sulph.	Apparently ceased.
H	Not recorded.	℥ii to ℥iii. On two successive days streaks.	112 to 120.	Not recorded.	Not recorded.
I	Early A.M. and P.M.	℥x to ℥viii on various days.	85 to 98.	Heroin, morphia, atropine, nitrites, ergot.	Ceased, then recurred. Advanced case; died from sepsis.
J	1.30 A.M.	℥ss to ℥iii. Recurrent.	74 to 98	Ergot, ice.	Raised blood almost daily for nineteen days.
K	A.M. and P.M.	℥i to ℥iv. Recurrent.	110 to 120.	Morphia, atropine, nitrite of amyl.	Apparently ceased. Slight spitting subsequently.
L	4 A.M. 3 P.M.	℥iii. ℥iv.	130. 130.	Morphia, atropine, Epsom salts; later, nitrites, ergot.	At once. At once. Thereafter many recurring hemorrhages.
M	Night and P.M.	℥ss to ℥iiss. Recurrent.	120 to 130.	Heroin, Epsom salts.	Ceased; in a few moments followed by clots.
N	9.20 P.M.	℥ss.	119.	Heroin.	Ceased at once, followed by clots.
O	P.M.	℥i to ℥ss for several days.	130	Nothing at first. Ergot later.	At once. Recurred. At once.
P	Early A.M. P. M.	℥ii to ℥xv over many days.	120 to 135 before nitrites; 115 after.	Morphia, atropine, ice, nitrites, calcium chloride, aconite, salts.	Ceased after nitrites and aconite.
Q	A. M. P. M.	℥ss to ℥iv. Recurrent and persistent streaks.	113 to 145.	Morphia, nitrites; finally ergot continued.	Gradually ceased after ergot.
R	Willis. Early A.M. P. M.	℥ss to ℥iii. Recurrent streaks.	90 to 125.	Morphia, atropine, ergot.	Apparently ceased after ergot until blood pressure fell again.

18 cases.

occur. In one of our cases this was done for several days before the occurrence of the hemoptysis, and it was found that a fall in the blood tension preceded the hemorrhage. Ergot was used in this case continuously for several days — as the hemoptysis was recurrent — and with apparently good effect.

I have referred to our experience, which is similar to that of others, that in the majority of cases the hemoptysis occurs at night, or in the early morning hours. In eleven out of sixteen of the reported cases it will be seen that this happened. This fact throws some light upon the cause of the hemorrhage and at the same time gives us a hint as to treatment. It would appear to indicate that the blood pressure and sudden variations in pressure were a causative factor. Lawrason Brown thinks that Howell's theory of sleep offers an explanation of this; this theory being, in brief, that sleep is due to the fatigue of the vaso-constrictor center, and, in consequence, there is a dilatation of the peripheral vessels, when, in the early morning hours, the vaso-constrictor center is regaining its lost tone, variations in blood pressure result. To prevent this variation and equalize the blood pressure, Brown gives morphia and sodium nitrite between midnight and 2 A. M. It will be noticed that calcium lactate or the cloride was employed in several cases, on the coagulation theory. The cases are too few, however, to draw any definite conclusions, but my feeling is that this treatment is of small value.

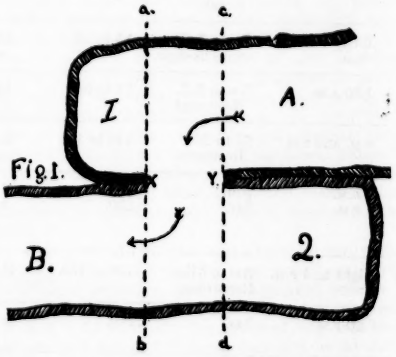
Epsom salts are frequently used in our service and with apparent benefit, probably, as Babcock says, on account of the favorable effect of a laxative upon the "pulmonary circulation through stimulation of the splanchnic nerves, which are known to regulate blood pressure throughout the body."

Aconite has also been employed, but I need further experience to judge of its value.

In conclusion, from the experience in these reported cases and from our general experience, I would suggest a plan of treatment of hemoptysis somewhat as follows — provided, of course, that any active treatment seems indicated: First, a knowledge of the blood pressure of the patient from previous observations. On the occurrence of the hemorrhage, ice, morphia and atropine subcutaneously, and, depending upon the amount and rapidity of the hemorrhage, the inhalation of nitrite of amyl. A laxative dose of sulphate of magnesia, and, if the bleeding persists, or is recurrent, nitrite of sodium or nitroglycerin if blood pressure is high for the individual, or, if low, ergotin subcutaneously.

I am quite well aware that when I suggest the use of ergot I am uttering heretical doctrine, but in our experience it has apparently proved itself of value in at least a few cases when other remedies have failed.

I have to express my obligations to my resident physicians at the sanatorium, Drs. Dunham and Crane, who have conducted the detail of these observations and to whose experience and suggestions I am greatly indebted.



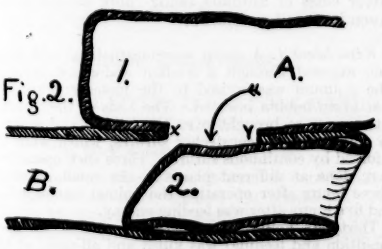
A SOLUBLE BOBBIN FOR INTESTINAL ANASTOMOSIS.

BY JOHN H. CUNNINGHAM, JR., M.D.,
Surgeon to the Long Island Hospital, Boston, Mass.,
AND
HAROLD W. BAKER, M.D.,
House officer at St. Mary's Hospital, Rochester, Minn.

ALTHOUGH intestinal anastomosis has been practised more or less since the fourteenth century, it has only been used with anything like satisfactory results for the last forty years. The introduction of aseptic surgery rather than any new method or device has brought it to its present state of perfection.

All intestinal anastomoses up to the fifteenth century were done with the aid of some mechanical device, *e. g.*, dry goose trachea, cylinders of cardboard, cylinders of fish glue and wood. Employing these devices, the cut edges of the intestines were approximated over the cylinders and sutured with a continuous unsterilized raw gut suture. These operations were not attended with much success, not only on account of the mechanical devices employed, but also on account of the resulting sepsis, although a few cases are recorded in which the patient survived.[1]

We find the surgeons of the eighteenth century speaking of all wounds of the small intestine as fatal, but saying that all wounds of the large intestine should be sutured. Until the middle of the nineteenth century very few satisfactory results were obtained. The feeling in regard to intestinal anastomosis at this time is very well expressed by Weinn's article in 1818, in which he says that "the process of intestinal suturing is a very dangerous undertaking and the mortality following this procedure is much greater than where the process of repair is left to nature's resources."

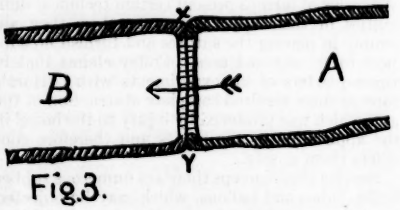


With the introduction of aspetic surgery began a new epoch of intestinal anastomosis. The subject received the attention of many surgeons from this time until the present day and many different mechanical devices have been advocated both for lateral and end-to-end anastomosis.

Until recently there has been no valuable data

as to the relative efficiency of lateral and end-to-end anastomosis,— a most important point.

Lately it has been proven by the experimental work of Cannon and Murphy [18] that in lateral anastomosis we get the following results (see Fig. 1): It will be observed that the circular muscular fibers cut at x, y, paralyzes the peristaltic movement between the lines a, b, — c, d; the food, however, is carried through this dead space, a, x, y, c, by the force of the stream behind. The food stream coming down the approximal portion of the intestine A is forced against the blind end I, and is not pushed through the opening x, y, until the pressure in part A is enough to overcome the obstruction between points x, y. After this blind end of gut has become filled the force behind pushes the food through the opening x, y, into intestine B. The food having gone through the opening x, y, is forced against the opposite intestinal wall b, d. As all the circular fibers are cut in the area x, y, there is another dead space at x, b, d, y. There are no peristaltic movements in this area to carry the food on, and when the food stream behind cannot force it, we get a stasis of food at this area. By feeding animals with food containing bismuth and studying their peristaltic movements by means of the Roentgen rays, Cannon and Murphy have proved that a stasis resulted in this area, and in a few cases in which indigestible food stuffs, *e. g.*, hay and hair are fed, an absolute obstruction occurred.



They found out further that another disadvantage of lateral anastomosis is that frequently in their experiments the peristaltic movement of the distal end 2 of intestine B, produced invagination of the blind end 2, closing the opening x, y, and thus resulting in complete obstruction. (See Fig. 2.)

In comparing the lateral method with the end-to-end method it can readily be seen that practically none of the circular fibers are cut and that the uninterrupted peristaltic wave forces the food by the line of incision x, y, into the distal portion of intestine B. (See Fig. 3.)

Thus in comparing these two procedures, we find that in the lateral method, stasis, subsequent dilatation and obstruction may result, while none of these factors arise in the employment of the end-to-end method. It is evident, therefore, that wherever it is possible the end-to-end method should be employed.

The technique of performing the end-to-end anastomosis is the next important question. Shall we simply suture the cut ends of intestine together, or shall we use a mechanical device to aid in the performance of this procedure? There is such a diversity of opinion in this matter that no definite statement can be made. The essentials in an end-to-end anastomosis are to complete the anastomosis quickly and to place the sutures accurately in order to prevent leakage and obviate a constriction at the site of the anastomosis. Operators familiar with intestinal work may

perform an end-to-end anastomosis as quickly and as accurately without as with a mechanical device, but it is fair to say that an operator doing an anastomosis for the first time can perform the operation quicker and more accurately with than without a mechanical device. It is very much the same problem as to whether one can darn a stocking quicker and better with or without a bobbin to sew over.

Without condemning anastomosis by simple nature, the rapidity and technique of placing the sutures is greatly facilitated when done over a bobbin of some other mechanical device. With a mechanical device we have the serous surfaces held in a position in which they are sutured. The device further serves as a conduit, thus minimizing any chance for leakage, as well as keeping the intestial lumen patent. There is a class of instruments the sole purpose of which is to prevent the escape of intestinal contents during the anastomosis.

These are applied to the intestines a short distance above the point of the incision and are not of actual service in performing the approximation. As it is the object of this paper to deal with only the latter class, they will not be considered here.

Mechanical devices of service in performing the anastomosis are best considered in three classes as follows:

1. Devices Which Aid in Placing the Sutures but Which are not Left in the Intestine.

Mudd's, Grant's, Lee's, O'Hara's,[7] Lepace's and Cabut's forceps. Wackerhagen's tube, Halsted's,[14] Praver's and Dorone's bulbs.

2. Unabsorbable Mechanical Devices.

Murphy's,[3] Graberini's, Juvara's and Jarborle's metallic buttons. Hayes's, Boari's,[9] and Ball's ivory buttons. Harrington's[4] and Granpazzi's segmented rings. Brochaw's and Caput's rubber rings. Collier's rubber tube. Clark's rubber bulb. Cazzini-Duplay's metal cylinder and Allingham's ivory tube.

3. ABSORBABLE MECHANICAL DEVICES.

Neuber's,[10] Bonnier's, Robson's [8] and Littlewood's decalcified bobbins. Ball's, Hayes's and Collier's decalcified bone buttons. Senn's [2] decalcified bone plates. Bailey's and Allingham's decalcified bone tubes. Jones's decalcified bone cones. Gill's decalcified ivory button. Abbe's catgut rings. Alexander's and Andrier's potato cylinders. Wackerhagen's [1] wafer cylinder. Metcalf's [12] sugar cylinder. Holenhausen's bread cylinder, and Bell's tallow cylinder. Cunningham's maccaroni bobbin.

Of the first class (*devices which aid in placing the sutures, but which are not left in the intestine*) the most prominent are the forceps invented by O'Hara, and Halsted's inflatable rubber bulb. All forms of forceps present certain technical difficulties in their application. Further, they aid simply in placing the sutures and furnish no support to the sutured area. Coffey claims that in three-quarters of his experiments with O'Hara's forceps there resulted complete obstruction of the gut, which was produced by injury to the bowel in the application of the blades and therefore considers them unsafe.

Besides these forceps there are numerous rubber bulbs, tubes and ballons, which may be objected to on the ground that having been introduced into the intestine sepsis may result by contaminating the surrounding area during their removal.

Of the second class (*unabsorbable mechanical devices*) Murphy's button, a most ingenious device as well as a most delicate piece of mechanism, stands out first and foremost and may be taken as the type. This button has been used most extensively and has yielded good results. The main objection to it, as well as to the other devices of this class, is that there is a heavy foreign body left in the intestinal canal, which may remain *in situ* and cause obstruction either by its lumen, which is small, becoming plugged, or by its weight, causing a sag or kink of the intestines. Another disadvantage of this button is the fact that its liberation depends upon the sloughing of the intestinal walls, which are clasped within the opposing edges, and that this sloughing may not stop at a point inside of the adherent surfaces, but may extend beyond and a perforation result. Numerous cases are on record in which the button has been found subsequently in the abdominal cavity. Moreover, the raw unhealed surfaces left within the bowel may become adherent or by contraction partially occlude the lumen.

Of the third class (*absorbable mechanical devices*) Neuber, in 1884, was the first to use one of these devices for intestinal anastomosis. He devised a bobbin of decalcified bone, which was inserted into the lumen of the intestine, the severed ends being drawn over the bobbin and a purse-string suture passed around each end to be approximated. While Neuber was the first to introduce the absorbable device, Mayo Robson's decalcified bone bobbin is the best known member of this class.

These absorbable devices have all the advantages of the unabsorbable ones and by their absorption can produce no after complications, disappearing, as they do, by the natural processes of digestion.

An ideal mechanical device to be used in end-to-end anastomosis is one which will insure the normal passage onward of the intestinal contents, one which can be easily inserted which will facilitate the rapid and accurate placing of the sutures, keep the lumen patent, hold the serous surfaces in position until they have become firmly adherent and then be digested or dissolved and pass off in the intestinal stream without producing any intestinal injury or after complications.

The idea of employing a maccaroni bobbin occurred to one of the writers (Cunningham) several years ago. Maccaroni recommends itself, because it is easily digested in the intestine, is cheap, and may be made sterile in its preparation. During the past four years it was employed experimentally with success, but no detailed observations recorded. A few months ago the writers, aided by Dr. W. E. Ladd, undertook a series of experiments to determine how long the bobbin remained undigested in the intestine, with the following results:

The maccaroni used was a large size commercial maccaroni, cut into cylinders 3 inches long by $\frac{3}{4}$ of an inch in diameter and bobbins of special design. (See Fig. 4.) These were sterilized by

Fig. 4

dry heat. The experiments were performed upon cats, dogs and sheep. The observation in the latter class of animals, being more accurate, are given in detail as follows:

Experiment 1. A sheep was anesthetized and intestine exposed through a median abdominal incision. The jejunum was incised to the mesentery and the maccaroni bobbin inserted. The ends of the inserted intestine were brought over the bobbin and sutured by interrupted Pagenstecher sutures, which were reinforced by continuous suture. Three such operations were done at different places in the small intestine. Three hours after operation the animal was standing and five hours after was feeding on hay.

Thirty-six hours after operation, aminal (in good condition and feeding) was killed and all three of the intestinal wounds were found to be healed, or at least to be firmly adherent. There was no leakage or sepsis. The maccaroni cylinders were completely disintegrated and no traces of them could be found in the intestinal tract.

Experiment 2. Operation same as Experiment 1. Three end-to-end intestinal anastomoses were performed over bobbins of sterile maccaroni, placed in different parts of the intestine. The edges were approximated as before.

Twenty-four hours after operation animal (in good condition and feeding) was killed. Intestinal wounds firmly adherent. No leakage or sepsis. The maccaroni bobbins had disappeared from the original site, but small pieces soft and partially digested were found in the intestinal tract beyond the points of suture.

Experiment 3. Operation. Two end-to-end anastomoses with maccaroni bobbin. Edges being sutured with only one continuous suture through all the layers of the intestine. Gastro-enterostomy was also performed with maccaroni as a mechanical device.

Twelve hours after operation animal (in good condition and feeding) was killed. The bobbin used in the gastro-enterostomy was found to have slipped into the stomach and was considerably softened although in no way disintegrated. The wound was clean but not as firmly adherent or in as good condition as the intestinal wounds. The bobbins in the intestine were found to be in position, considerably softened but not disintegrated. The serous surfaces were adherent and no leakage or sepsis was present.

These experiments tend to show that in the maccaroni bobbin we have a device which, besides facilitating intestinal suturing and holding the sutured ends in position until firmly adherent, serves as a conduit for the intestinal contents and at a period of time not under twelve hours or later than thirty-six hours, is digested and absorbed.

Clinical Department.

VICARIOUS MENSTRUATION WITH A REPORT OF TWO CASES.

BY RALPH C. LARRABEE, M.D., BOSTON.

VICARIOUS menstruation is such a rare condition that some have denied its existence. A study of the literature certainly leads to the conclusion that many of the reported cases are spurious. Still there are many others that hardly admit of a doubt, cases, for example, where vicarious bleeding has occurred regularly for years, but has always ceased during pregnancy. The condition has occurred at all ages from the first menstrual period to the menopause. Some patients show pelvic abnormalities obstructing the flow, while in others the pelvic conditions have been normal. There is great variability in the site of hemorrhage, some bleeding from the nose, some from the lungs, stomach, rectum, eyes, ears, gums, bladder, nipples or umbilicus. In some the bleeding has been confined to a nevus, a scar, a fistula or a leg ulcer. Usually the hemorrhage occurs from but one site, but a few cases have occurred in which at regular intervals corresponding to the menses there has developed a tendency to bleed in various if not in all situations. Such a case is the following:

CASE I. Mrs. E. F., aged thirty-six, applied for treatment at the Medical Out-Patient Department of the Boston City Hospital on Dec. 1, 1903. There was nothing of importance in the family history, particularly no hemophilia. She had two children, a boy and a girl, neither of them bleeders. The patient was born in England and came to America in 1898. Apart from an indefinite history of an attack of "inflammation of the bowels" she had always been well. She used liquor freely, frequently to the point of intoxication. The menstrual history was, up to the onset of her final trouble, normal.

In the summer of 1902 she began to suffer from menstrual irregularity and in December of the same year normal, uterine menstruation ceased wholly only to be replaced by the phenomena for which she sought relief. At more or less regular intervals, averaging somewhat less than four weeks, a dark colored rash would appear on the legs and more sparsely over the rest of the body. At the same time she would have nose-bleed and "blood-blisters" would appear on the lips, gums and tongue. Each attack lasted but a few days. Each attack left her paler and weaker than before, and in the intervals she did not regain her previous health. She complained also of headache, dyspnea, puffiness of the face and swelling of the feet. The bowels moved daily and the appetite was good. Her diet was ample in amount and mixed in character, including an abundance of fresh fruit. When first seen she was recovering from a severe attack.

Physical examination showed a well-developed and well-nourished woman in good general condition, but very pale. The area of cardiac dullness was slightly increased and there was a systolic murmur at the apex transmitted a short distance towards the axilla. The lungs, abdomen and abdominal viscera were normal. There was a fading hemorrhagic eruption, most marked on the legs, a large ecchymosis on the back of one hand and several small, hemorrhagic vesicles on the tongue and lips. The urine was normal.

The blood was as follows:

Hemoglobin, 45%; red corpuscles, 1,520,000; white corpuscles, 5,400.

A differential count of white corpuscles showed nothing abnormal. The most marked features of the smear were the achromia and the small number of platelets. No nucleated reds were seen. The coagulation-time was not studied, but the bleeding from minute punctures was unusually free and clotting appeared to be much retarded.

She was given iron, arsenic and calcium chloride and instructed to take in her food as much gelatin as possible. She steadily improved and at the end of a week there remained no evidence of the hemorrhages, except for the rapidly diminishing anemia.

The patient had prophesied her next attack for December 20, and as this date approached she was observed with both interest and skepticism. On the 21st she presented herself at the clinic in a condition that removed all doubts. There was a purpuric eruption on the legs and fore-arms, with a few spots on the trunk. There was slight bleeding from the mucous membranes of the nose and mouth. On the whole the severity of the attack was much less than before. She was not seen again until March 7 when she returned to the hospital in the midst of a very severe attack. She stated that in the interval she had had two others.

A second blood examination was made on March 11, with the following results:

Hemoglobin, 45%; red corpuscles, 2,912,000; white corpuscles; 15,100.

A differential count of white corpuscles showed nothing abnormal. There were no nucleated reds. There was marked achromia and marked variation in the size of the reds, the average being noticeably small. There was moderate poikilocytosis and slight polychromatophilia.

The woman was advised to enter the wards for the purpose of further study and treatment, but refused. She soon after became a patient of the Suffolk Dispensary. I am indebted to Dr. Clark of that institution for the information that the hemorrhagic attacks continued to occur at intervals approximating the menstrual periods. Each month she appeared to lose more than she regained and she finally died in an attack on Dec. 3, 1904.

To summarize: We have a woman who menstruated normally up to the age of thirty-five, when, without previous history of hemorrhages, menstruation ceased and she began to have regular, periodic attacks resembling hemorrhagic purpura. Severe, and finally fatal, anemia resulted.

There is nothing in this history to suggest hemophilia. There was no general, permanent tendency to bleed, no suggestion of the disease in the ancestors or children. Cuts and wounds healed as in normal individuals. Moreover, the age of onset is greater than in hemophilia, which rarely begins later than twenty-two.[1] Another condition which predisposes to hemorrhages in various parts of the body is cirrhosis of the liver and in this case the alcoholic habits of the patient strongly suggest its presence. The suspicion, however, could not be verified, and at best such a diagnosis would leave unexplained the close relationship between the hemorrhages and the menstrual periods. The physiology of normal menstruation is as yet but poorly understood, and one is certainly not justified in saying that in the case herein reported the periodical hemorrhages accomplished a function that would otherwise have been brought about by the normal uterine flow. In making the diagnosis of vicarious menstruation one merely registers the fact that the attacks resembled in their periodical occurrence the normal menses, which ceased when the attacks began, and that they were therefore somehow connected with that function. That they were truly vicarious in a physiological sense cannot be affirmed.

A review of the literature of the last twenty-five years shows very few cases like this one. Heitzmann,[2] in 1884, collected a number of cases of menstrual exanthemata, some of which were purpuric. In certain of these cases there was atrophy, under-developement or other marked anomaly of the uterus causing obstruction, and in one or two of these local treatment resulted in recovery. Rouvier[3] quotes Puech to the effect that out of 200 cases of vicarious menstruation 8 were from multiple sites, while out of the 334 collected by Rouvier 4 were from all parts of the body. In 1888 Butler[3] reported a case of a woman of alcoholic habits in whom the menses ceased for nine months. A general, hemorrhagic, vesicular eruption, together with bleeding from the nose and throat, occurred during this time, but it is not clearly stated that the attack recurred regularly at each catamenial period. She recovered.

I have found but four cases where, in place of the normal uterine flow, there occurred periodically a condition resembling the severe type of hemorrhagic purpura.

1. Barnes[4] described a case of Clark's. A woman of eighteen who had never menstruated began to have attacks every month of bleeding from the gums and nose and occasionally from the stomach, together with a purpuric eruption. She finally died of severe anemia in an attack. An autopsy showed, in addition to extensive hemorrhages in the internal organs, a rudimentary uterus and normal ovaries. In one of the latter was a recent, false corpus luteum.

2. Andrade (quoted by Barnes[5]) described a case in which hemorrhages from the stomach, nose, gums and skin replaced the normal menstrual flow. "Menstruation returned."

3. La Forte (quoted by Heitzmann[2]) reported the case of a woman of twenty-six who had had, since the age of fifteen, menstrual molimina, without actual flowing. At regular intervals there occurred bleeding from the lungs, nose and skin. The vagina was congenitally absent. A successful operation for the formation of a new vagina completely relieved the symptoms, normal menstruation being re-established.

4. Quite recently Schechner[6] has reported a case almost exactly like mine. A woman of forty-seven suddenly ceased to menstruate, the normal flow being replaced by subcutaneous hemorrhages and nose-bleeds of great and increasing severity. She finally died in an attack.

Fatal cases of vicarious menstruation are rare. In addition to the cases already referred to there are, in the older literature, a few dubious instances. In some of the cases reported as fatal, death was only in an indirect way due to vicarious menstruation. Kober,[7] for example, reported a woman with incipient tuberculosis in whom the normal uterine flow was replaced by regular, vicarious hemorrhages from the lungs. Each attack was followed by an acute process in the lungs. The patient finally died, but death was not a direct result of hemorrhage. In 12% of Rouvier's cases the vicarious bleeding was from a cancer of the stomach or a tuberculous focus in the lung. Two others died directly of hemorrhage, making a total mortality of 14%.

The following case represents a much different type:

CASE II. Miss S. J. C., age twenty-nine, a nurse. For the opportunity of reporting this case I am indebted to Dr. J. N. Coolidge, to whose service at St. Luke's Home she was referred by Dr. S. M. Gordon, of Fall River.

The patient knows of no bleeders in her family. Two brothers and two sisters are living and are not bleeders. She knows nothing about her mother's father, to whom one would naturally look for a history of hemophilia. She has no maternal uncles. Her

mother died with paralysis of both legs; she may have been syphilitic. No ancestors on her father's side were bleeders.

As long as the patient can remember she has been subject to severe nose-bleeds. She says that cuts and wounds bleed more with her than they do with others, and, as a child, she was always obliged to lie down when she cut her finger and hold it up. Blows always leave large ecchymoses. She once had a severe hemorrhage after the extraction of a tooth and was once in danger of her life as the result of bleeding from a wound on the leg. The resulting scar, however, indicates a wound of sufficient magnitude to be serious in a normal person. Seven years ago an abscess was opened without undue loss of blood.

Menstruation began at the age of twelve. The first period lasted two weeks and she lost a dangerous amount of blood. She continued to menstruate irregularly about every two weeks. Each time the uterine flow was preceded by nose-bleed for several days and was generally accompanied by bleeding from the gums. For the past four years there has been also a purpuric eruption. She never noticed blood in the urine, feces or sputum. She once vomited some black material that she thought was blood. The uterine flow was commonly severe, from six to twelve napkins being used. Sometimes the loss of blood was so severe as to incapacitate her for several weeks. These attacks occurred about once a year, always in cold weather.

She was first seen by the writer on Feb. 2, 1906, during a menstrual period which had commenced with a nose-bleed. Examination showed an apparently healthy young woman in good general condition and not pale. The only evidence of abnormal bleeding was a few small petechiæ on the fore-arms. The thoracic and abdominal viscera and the reflexes were normal.

An examination of the blood showed a normal percentage of hemoglobin and normal numbers of white and red corpuscles. Stained smears showed no abnormalities either in the differential count of leucocytes or in the morphology of the red corpuscles. The coagulation-time by the Brodie-Russell method was twenty-one minutes. The normal time by this method, according to Pratt, is four or five minutes.[9]

A guaiac test for blood in the feces, after abstinence from food containing hemoglobin for three days, was faintly positive.

Under treatment she improved rapidly, but the loss of blood at the menses continued to be excessive and the intervals short and irregular so that she was flowing more or less all the time. A day or so before each exacerbation of the uterine flow she always had nose-bleed and fresh crops of petechiæ. She was seen in April by Dr. Edward Reynolds, who found both ovaries diseased and recommended operation. Ovariotomy was performed by Dr. Wadsworth. The left ovary was triple the normal size and was cystic; it was removed without the tube. The right one was also enlarged and adherent with the tube to the back of the broad ligament. With some difficulty it was separated from its adhesions and removed with the distal half of the tube. There was considerable oozing from the bed of this ovary and from the two small punctures in the uterus made with the French hooks. The hemorrhage was not in any way alarming. Convalescence was perfectly uneventful.

For the first two or three months after the operation at the times when the menses were expected, she had slight nose-bleeds and hemorrhages from the gums, with a few spots on the skin. Then without any periodicity she continued to have occasional slight nose-bleeds and spots. About eight months after the operation she menstruated profusely, but had no accompanying hemorrhages from extra-genital sources. She was recently seen by the writer and appeared to be in excellent health. The coagulation time was nine and one-half minutes.

To summarize this case: A young woman, without family history of hemophilia, gives a story of a tendency to hemorrhagic conditions from early childhood. The first menstruation is accompanied by menorrhagia and thereafter each period is associated with an exacerbation of the hemorrhagic diathesis. Ovariotomy influences the periodicity but does not altogether abolish the tendency to hemorrhages.

This case is probably to be regarded as one of mild hemophilia, since the bleeding from the skin and mucous membranes at the time of the menses was merely an intensification of a permanent, though not well marked, hemorrhagic diathesis. It is a well-known and generally acknowledged fact that hemophilia is a disease of the male sex. But this rule is not an invariable one. Particularly if these mild forms are taken into account, the classical statement of Grandidier,[10] to the effect that only one bleeder in thirteen is a female, must certainly be modified in favor of the greater frequency of the disease in that sex.[11] The onset of the disease in this case in childhood is in accord with the generally observed facts in hemophilia. The fact that she was operated upon without undue loss of blood does not nullify the diagnosis, since bleeders quite frequently show the tendency to unusual hemorrhages only at certain periods. Litten[12] says that large surgical wounds are less apt to bleed dangerously than trivial ones, and even refers to a case in which Fordyce stopped a hemorrhage in a bleeder by enlarging the wound. According to Grandidier, women with slight hemophilia show little tendency to traumatic hemorrhage.

Female bleeders quite commonly suffer from profuse menstruation, but a study of the literature leads to the conclusion that there is not commonly at the monthly periods any increase in the tendency to bleed from other sites, such as was shown in my case. In some published instances, however, such exacerbations of the hemorrhagic tendency have occurred. Kehrer,[13] in 1876, mentioned three cases from the literature in which female bleeders had unusually severe manifestations of their disease at the time of the menses. Köhler[14] refers to a hemophilic woman who had severe bleeding from "all orifices," a few days before each period. Hadden[15] has reported a girl of fourteen in whom there was no family history of hemophilia. Purpuric spots had been observed at times for five years. There had been unusually severe hemorrhage from slight wounds, and two severe nose-bleeds. The first menstrual period was very severe and prolonged, and caused marked anemia. Blood punctures from the ears bled several days. There was a general purpuric rash. A subsequent menstrual period was associated with an abnormal loss of blood, but there were no petechiæ. The author considered the case one of hemophilia.

Extra-genital hemorrhages recurring at the

menstrual periods fall naturally into three groups, of which the two more unusual ones are illustrated by the cases herewith reported.

In the first and commonest form the uterine flow is replaced by bleeding from some other site, but there is no general hemorrhagic tendency. Such cases usually run a favorable course, so far as the general health is concerned, the vicarious hemorrhage causing no more unfavorable symptoms than normal menstruation.

In the second form, typified by Case I, the normal flow ceases and there is a general hemorrhagic tendency, with a picture like purpura hemorrhagica. The resulting anemia may prove fatal.

The third form, typified by Case II, is probably to be regarded as closely allied to, if not identical with, hemophilia. In the few cases recorded a family history of this disease is often lacking, but there are several common and suggestive features. There is generally a history of purpura, nose-bleed or severe bleeding from trivial wounds in childhood. The first menstrual period is apt to be associated with severe menorrhagia. The cases are spoken of as vicarious menstruation merely because, along with the normal monthly flow, there may be an exacerbation or a tendency to bleed present at other times as well. Uterine menstruation is absent in some cases, but in others, as in ours, it is excessive.

Surgeons are naturally and properly loth to operate on these cases of hemorrhagic diathesis. Yet it is natural to expect that ovariotomy will give relief where the condition shows a periodicity corresponding to the menses. Bartlett[16] removed the ovaries from a woman in whom normal catamenial flow was replaced by periodic bleeding from the stomach, the operation being undertaken for other surgical indications. Two months after operation the vicarious bleeding recurred and continued at regular intervals of three or four weeks. This is the only case I have been able to find where ovariotomy was done in a case of vicarious menstruation. The case obviously belongs to the first group of the classification suggested above. In my Case I, operation seemed very promising since the hemorrhagic diathesis existed only at the menstrual periods, and yet the loss of blood was such as to cause a progressive anemia. In cases where vicarious menstruation is merely a manifestation of hemophilia, operation is to be undertaken with more timidity, and is of course not to be thought of in severe cases. It promises fairly certain relief from one source of hemorrhage, viz., uterine menstruation, and it offers a probability of relief from the periodic exacerbations of the hemophilic tendency.

SENILE TREPIDANT ABASIA. REPORT OF CASES.

BY E. W. TAYLOR, M.D., BOSTON.

THE following cases are reported to draw attention to a peculiar disturbance of gait occurring in elderly people and presumably associated in some as yet inadequately explained way with general arterio-sclerosis:

CASE I. Mrs. C., eighty-three years old, was first seen Oct. 22, 1903. She gave the following history: Up to three years before she had considered herself well, except for the natural infirmities of advancing years. At that time she began to notice a disturbance in walking, particularly characterized by difficulty in starting. At times, when once started, she was able to progress fairly well, but the first movements necessary to taking a step were very much hindered, particularly when embarrassed by the presence of any one in the room. Going down a certain flight of stairs had become increasingly difficult and at the time of my first visit was impossible. The patient felt that she was growing worse.

Physical examination showed equal pupils with adequate light reaction, normal heart and no definite radial arterio-sclerosis so far as could be determined by ordinary methods of examination. The hand grasp on both sides was good; the reflexes of the arms lively, but not markedly different, with a probable slightly greater reaction on the left than on the right. The knee-jerks were both active, with a questionable Babinski sign on the left. No plantar reflex was obtained on the right. There was slightly greater difficulty in moving the left leg than the right. In general the patient appeared vigorous for one of her years and gave no indication of definite local or general disorder.

The point to which I desire to draw particular attention is her difficulty in locomotion. When standing and asked to take a step forward, it was practically impossible for her to do so by an ordinary act of the will. After much difficulty, hesitation and "muscular stammering," she was finally able to start the muscular movements necessary to walking, and still with much difficulty, taking short and uncertain steps, she was able to progress a certain distance with much show of effort. There was in this case no element of spasticity nor ataxia, nor could it in any sense be regarded as the gait of ordinary feebleness. The disturbance in locomotion, in other words, was out of all proportion to the other symptoms which she showed.

Certain exercises were prescribed which she followed out with faithfulness and with certain definite temporary improvement. When seen two weeks later she was distinctly better and was able to a certain extent to walk alone. At this time she complained of difficulty in writing very similar in character to that of walking. She was able to copy and write spontaneously correctly, but only after much effort.

She was seen again two years later, and during the interval had grown decidedly more feeble. She complained of spasmodic twitching of the legs at night sufficient to keep her awake. The reflexes were very active, still there was no ankle clonus, and the Babinski sign was altogether indefinite. As at the previous visits the left side showed slightly greater involvement than the right. The heart was arythmic and feeble; the

pulse 100; the radial artery stiff. She had practically given up the attempt to walk. Except for general enfeeblement, there was still no definite sign of intracranial or spinal disorder of a gross sort.

Case II. Mr. M., referred by Dr. J. E. Goldthwait, Nov. 9, 1906. The patient was seventy-five years old, without occupation. He had not worked for four years, and had had difficulty in walking for from one and-one half to two years. He complained that he "couldn't do as he used to, couldn't handle his limbs, which were like sticks." His legs, he said, gave out, and his ankles had swollen for six months past. He had, however, no subjective disorder of sensation; was able to sleep and eat well. He was slightly deaf through thickening of the drum membrane, but was not troubled either by headache or vertigo. He had noticed some shortness of breath and a sense of pressure across the chest, but there was no cough in the morning or at any other time. He thought that his left leg was more affected than his right, and complained of stubbing his toes through difficulty in lifting his feet. There was no definite pain in his legs, but occasionally he had sharp twinges running down his legs which he called rheumatism, from which he had suffered to a greater or less extent for some years past. He complained also of frequent micturition and lack of perfect control, especially when nervous. He had also been much annoyed by a tendency to emotionalism which manifested itself by crying again and again through the examination.

Physical examination was in general as follows: Pupils were equal, with good light and accommodative response; no disorder in the distribution of the cranial nerves; the strength of the arms was normal, with slight reflexes; they showed no motor or sensory disorder; pulse was 80; the heart sounds clear, with both the aortic and pulmonic second sounds sharply defined. There was a pseudo-Romberg sign; no general loss of sensation, and a doubtful disturbance in the muscular sensibility of the right great toe. Knee-jerks were within normal limits and essentially equal. There was no Achilles, clonus or Babinski sign. The normal plantar reflex was slightly developed. The strength of the legs was good. Examination of the urine showed no significant abnormality. Here again the striking peculiarity was the difficulty in locomotion without any apparently adequate underlying cause in the central nervous system. The same difficulty in starting and in progressing as described in the preceding case was found. The disproportion between the physical signs of disorder either in the motor or sensory tracts and the disturbance in locomotion was very striking.

Case III. Mr. D., approximately seventy-two years old, was seen Nov. 30, 1906, in consultation with Dr. D. W. Cheever. The patient for the most part had led a sedentary and studious life, and for some years past had shown the inroads of time by general failing in strength. Physically he was handicapped by a marked curvature of the spine, rigidity of the spinal column and of the bordering muscles. He had presumably had two slight hemiplegic attacks in preceding years, one on each side, from which he had in general recovered.

Physical examination showed a high degree of radial sclerosis with somewhat weak heart sounds. The knee-jerks were active, but there was no Babinski phenomenon and no evidence whatever justifying the supposition of a systemic degeneration of the pyramidal tracts. Although the patient in general presented many indications of advancing years, these were wholly out of proportion to the extraordinary disturbance of gait from which he suffered and which had virtually made him a prisoner in his house. There was no paralysis of the legs, and in general the muscular strength was sufficiently good. In spite of this fact there had been increasing difficulty in locomotion, characterized by extreme difficulty in starting, a tendency to shorten the steps more and more as progress was made, and the incapacity to make a movement forward of more than a few inches. The patient is obliged often to stop, after going a few yards, tired with the great amount of muscular effort which he has been called upon to make. This disturbance of gait is absolutely analogous to that observed in the previous cases, and like them is out of proportion to the general physical disability.

A fourth case comes to mind of a hospital patient, an elderly man, who presented the same characteristic disturbance. The exact records of this case are not at hand, but the vivid remembrance of the gait disturbance unquestionably justifies placing it in the same category as the cases described. He found the same difficulty in innervating the muscles necessary to start the movements of walking. If left to himself, he likewise found the greatest difficulty in progressing, although much assisted, as, in fact, all these cases were, by encouragement, explanation and method.

The foregoing striking disturbance of gait, as seen in these cases, is undoubtedly the condition described many years ago by Charcot, as senile trepidant abasia. This disturbance has been rather overlooked in the intervening years, no doubt from the fact that it comparatively rarely occurs in the characteristic form which is unmistakable. In a paper read before the American Neurological Association in June, 1906, Collins discussed the question of "A definite clinical variety of a cerebral arterio-sclerosis," [1] and drew a picture which he regards as pathognomonic of cerebral vascular disease, even although no external signs of arterio-sclerosis appear. With this picture those who have had much to do with elderly patients, as seen, for example, in almshouses, are familiar, though the clinical picture may not have been so clearly defined in their minds as that which Collins draws. Speaking of the disturbance of gait observed in his patients, Collins regards it as not unlike and possibly identical with the trepidant abasia of Charcot. In one place Collins describes the gait as follows: "When he (the patient) attempted to walk, the feet wide apart, shuffled along the floor a few inches at each stride, the strides sometimes fast, sometimes slow, while he made balancing movements with the hands." In this description no reference is made to the stammering character of the gait, the inability to start, and the curious ineffectual attempts to make progress. It is, however, probable that the gait to which Collins refers, represented rather a difference in degree than in kind from that which I have described in the foregoing cases and which Charcot, no doubt, had in mind when he gave to it the name "trepidant abasia." However, this may be the gait, when fully developed, is unique and unmistakable.

The best discussion of this type of disturbed locomotion which I have seen is given in a recent exhaustive paper by Karl Petrén, in which he deals with the relation between disturbance of gait in old age, produced by anatomical lesions

[1] Collins: Jour. Nerv. and Ment. Dis., 1906, xxxiii, 750.

and by functional disorders.[3] In this article, to which Collins also refers, Petrén accurately describes the gait disturbance to which I wish again to call attention. His general conclusions are that arterio-sclerosis lies at the basis of the disorder, but that it cannot be said that the disorder of gait is directly due to the changes in the blood vessels. On the other hand, hereditary influences and hysterical conditions are not to be seriously considered. The explanation of the disturbed locomotion, according to Petrén, is that the sclerosis of cerebral vessels brings about a mental state producing a subjective feeling of difficult locomotion which then has a pathogenetic effect in the production of a "Vorstellungskrankheit," in other words, the disturbance of gait is directly produced by a feeling of incapacity superinduced by structural, vascular changes.

However fanciful such an explanation may be, the type of disturbance certainly demands something more than a mere physical reason for its existence. Examination of the patients shows no sufficient physical incapacity to account for the gait. There is no paralysis; movements in other positions may be made with comparative ease and freedom; the individual muscular movements of walking may likewise be accomplished without difficulty, but the entire act of taking steps voluntarily results in the stammering tendency to which allusion has repeatedly been made. Explanation, encouragement and instruction, on the other hand, quickly produce results, and it is not difficult to induce such patients to walk with comparative ease through the use of such simple means. It is, therefore, apparent, as Petrén maintains, that we have in this interesting disturbance to deal with a mental defect, presumably dependent upon the senile changes of cerebral vessels which have, however, not led to sufficient injury to produce marked degeneration of the motor tracts.

At this time, when the general subject of arterio-sclerosis is demanding much attention, it is worth while to call attention to this trepidant abasia of the aged as illustrative not only of the infirmities which the vascular lesions themselves produce, but also as demonstrating the probable secondary effects upon the mind, which in turn lead to a lack of confidence, finally resulting in a practical incapacity for voluntary walking movements. The interest of these cases, therefore, lies not so much in the gait disturbance itself, as in the curious chain of events which finally brings it to pass. Much may, no doubt, be done in the way of treatment by perseverance, both on the part of patient and physician, in retraining the motor functions through an appeal to the will.

TUBERCULOSIS IN LONDON.—Notwithstanding its fogs and supposedly unhealthful climate, London has a lower mortality from tuberculosis than many other European capitals. In 1904 it was only 166 per 100,000 inhabitants, as against 257.5 in Berlin, 254 in Milan, 256 in Madrid, 314 in Vienna, 383 in Paris, and 387 in Moscow.—*Med. Record.*

WHEN the determination of arterial blood pressure first came into vogue as a common clinical procedure, there was a very great interest in this subject and many papers were published about it. As is often the case with a new method, extravagant claims were made as regards its value in diagnosis and treatment. Since then somewhat of a reaction has taken place and there has been a tendency on many sides to greatly discredit the value of blood pressure determinations. However, they have a distinct value, and during the year ending July, 1907, a number of contributions, to our knowledge, of blood pressure values in various conditions have appeared. The more important of these will be reviewed here.

In considering blood pressure it is important to distinguish minimal or diastolic blood pressure and maximal or systolic. Most of the early instruments were intended to record the latter and a large amount of our accumulated knowledge of blood pressure concerns only systolic pressure, whereas at present we know that, without a knowledge of both, we are unable to form a satisfactory judgment of the condition of the cardio-vascular system. G. A. Gibson [16] has admirably discussed the various methods of estimating blood pressure. For the systolic pressure we have the instruments of v. Basch and Potain which act by local obliteration of the pulse as judged by applying the finger or some recording apparatus immediately beyond the point of application of the instrument, the Riva-Rocci instrument or some of its modifications (Cook, Martin, Stanton, Janeway) with a cuff which encircles the arm and so obliterates the pulse, the apparatus of Gärtner which obliterates the pulsation in one of the fingers, and other forms.

For determining both systolic and diastolic pressure the instrument of Erlanger is the most accurate but it is expensive and rather bulky. Diastolic pressure can be determined approximately with the Riva-Rocci group of instruments by noting the point at which the mercury oscillations are greatest (Janeway), by taking pulse tracings of the wrist and noting the level below which no further increase in the size of the pulse wave occurs (Sahli), by palpating the pulse and determining the point at which it regains its maximum beat (Strasburger). The first method is only satisfactorily applicable to a fairly large pulse, the second requires much time and care, the third is in very general use in Germany and is accurate after practice within a limit of variation of 5 to 10 mm. of mercury. As pointed out by Hirschfelder,[21] one source of error in the Strasburger method lies in the lack of uniformity of pressure exerted by the palpating finger upon the radial artery, but this error can largely be eliminated by laying the tips of the index and middle fingers on the lower end of the radius just lateral from the artery and palpating the pulse with the balls instead of with the tips of the fingers. Under these conditions variations of pressure by the fingers are exerted against the bone and not against the artery and the main source of inaccuracy disappears. Bingels has constructed an instrument for determining diastolic pressure which is a combination of a mercury manometer and sphygmograph with a recording apparatus which by means of the break and make of an electric current as the mercury rises or falls marks every 10 mm. of change in pressure. This appears cumbersome and seems to be less efficient than the Erlanger apparatus.

The question naturally arises, Is any instrument necessary to determine blood pressure; is not the palpating finger sufficient? Gibson [16] expresses himself very strongly on this point as follows: "We sometimes, even in this new country (America), hear it said by distinguished teachers that the educated finger is the best means of judging the arterial pressure; to the initiated such a statement is grotesque in the extreme. Undoubtedly the sense of touch, aided by a long experience, is of considerable value, and it is the duty of each of us to train the fingers to the best of our ability; yet the man who will gravely say that he is able to gauge the blood pressure by means of his fingers is quite as foolish as another man would be who gravely stated that he was able to take accurate temperature readings by applying his hand to the surface of the patient. During the last thirty years my efforts in training myself to assess blood pressure by the sense of touch have taught how extremely fallacious such a method must always be. . . . Those teachers who still oppose the use of our modern instruments of research in the investigation of blood pressure are on the same level as those who contemn the employment of such instruments as the ophthalmoscope."

Schilling [28] as the result of more than 1,000 observations on 350 individuals states that often the finger is deceived and that instrumental measuring of the blood pressure is necessary for any degree of accuracy. This has been the experience, I am sure, of almost all who have used some one of the instruments for the determination of the blood pressure and the discrepancy is frequently much, so that a patient judged by the finger to have a moderately high blood tension is found to have a very high tension. As an example of this there were recently at the Carney Hospital

two patients in nearby beds, both nephritic cases. To the palpating finger of several observers there appeared to be no very great difference in blood pressure. Yet as determined by the Erlanger sphygmomanometer the one had a systolic pressure of 130 and diastolic of 90, the other a systolic of 220 and diastolic of 130. In each considerable edema was present and of about equal mount.

However, not all would agree with Gibson, as the following quotation from Broadbent [6] indicates. "It is by the radial pulse that we estimate clinically the pressure in the arterial side of the circulation, and it affords the educated finger information which, intelligently interpreted, goes farther and is more valuable than the instrumental registration of the blood pressure." A similar view is taken by Steven [33] who says, "But for the practical physician, in the investigation of blood pressure, the trained finger must be the ultimate appeal and it is, I hold, sufficient. It can give information of a kind and of a value in practice as a whole that no instrument, however ingenious, can supply."

To read between the lines of these expressed views of Gibson, Broadbent and Steven it would seem to me that they are talking in reality about slightly different things. Gibson and the adherents of blood pressure machines refer to the estimation of blood pressure alone, while the other group have in mind a number of qualities of the pulse determinable by the palpating finger and which give valuable information as to the condition of the cardiovascular system. No one would claim it advisable merely to register the blood pressure and not feel the pulse. The former gives a measured factor which in conjunction with other observed characteristics of the pulse is of great value. The blood pressure factor cannot be accurately quantitated except by means of instruments. To know the systolic and diastolic pressure in many cases is of great aid in diagnosis and prognosis.

As is now well known the width of cuff used with the Riva-Rocci form of apparatus is a source of variation in the results, as the narrow cuff gives high readings. Schilling [28] and a number of others have clearly demonstrated this. Schilling has further shown that the decrease in the height of a blood pressure reading decreases as the cuff is made wider until a width of 12 cm. is reached, beyond which there is practically no further change. With a cuff of that width the estimated systolic blood pressure closely approximates the actual intra-arterial systolic pressure. Another source of variation is the size of the patient's arm. Schilling has shown this by making readings on both arms of patients in whom one arm was larger than the other; the larger arm gives higher blood pressure values.

It is also important when making successive estimations on the same individual to have identical conditions each time since the ingestion of food, physical and mental exertion, and posture, influence blood pressure. There appears also to be a diurnal fluctuation. Change in posture effects especially the diastolic pressure.

Dawson [11] emphasizes the importance of qualifying the term "blood pressure" by the words systolic or diastolic, whichever is meant, and he insists on the necessity of determining both in order to understand the condition of the cardiovascular mechanism. The result of the neglect of this is illustrated experimentally in an animal by opening the abdomen, handling the viscera and allowing the peritoneal layers partially to dry. Under these conditions severe shock is produced. Yet systolic blood pressure falls but slightly. Diastolic pressure, on the other hand, rises and there is a considerable decrease in pulse pressure (the difference between systolic and diastolic pressures). The importance of knowing both systolic and diastolic pressures as determined in the brachial artery of man by means of sphygmomanometric methods is, according to Dawson, that from them we obtain the pulse pressure which, multiplied by the pulse rate, gives the systolic output per minute and is a measure of cardiac activity, since the pressures so measured in the brachial artery are equal to the lateral pressures in the aorta. This assumes that the pressure measured in the brachial artery is the end, not the lateral pressure. Bing,[4] on the other hand, maintains that the lateral pressure in the brachial is measured since, were it the end pressure and so the lateral pressure in the aorta, the pressure in the two arms would be equal, which is often not the case. Bing by a special apparatus shows that the pressure obtained depends in part on the state of contraction of the vessels of the arm and these changes do not necessarily represent changes in aortic pressure. So we are not dealing with the absolute systolic pressure according to Bing when we measure the brachial pressure by a sphygmomanometer. However, the values certainly are closely approximate and may be used as a measure of cardiac output.

H. J. Starling [32] with the Riva-Rocci instrument has studied the systolic pressure in cardiac cases. In many he finds hypertension, in none a pressure below normal. This is again evidence of the importance of the estimation of diastolic pressure, for without it we do not know the pulse pressure which is an index of the cardiac condition. According to Fellner [15] the particular value of pulse pressure determinations in cardiac cases is in connection with an estimation of the results of digitalis therapy, for a rise in pulse pressure indicates good effects from the drug, whether systolic pressure rises or falls. In aortic insufficiency, however, the variations in pulse pressure are of slight prognostic importance since many disturbing factors enter, but a high pulse pressure is of diagnostic value. In arteriosclerosis the results are very confusing, and pulse pressure determinations are of comparatively little value.

Blood pressure estimations, according to Rumpf,[26] may aid in the diagnosis of traumatic neurosis, since in such cases with tender points pressure over them leads to a rise or fall in systolic pressure along with other phenomena as acceleration of cardiac activity, decrease in size of

pulse, irregularity of pulse and cyanosis of the face. These all vanish shortly after cessation of the stimulation. In neurasthenics organic cardiovascular lesions can be excluded with great probability if, after a graded amount of work, the changes in blood pressure and cardiac output remain within normal limits (Stursberg [36]). This may help in distinguishing nervous and organic cardiac disturbances. Bing [4] finds that the symptoms of hypertension, variability and liability of blood pressure and pulse rate, and abnormal activity of the trigeminus reflex (blood pressure changes following the inhalation of weak acetic acid vapor) singly or better in combination are a frequent finding and in a sense of diagnostic value in vasomotor neuroses, especially those of traumatic origin. However, this group of cases usually has other evidence of their nature such as tachycardia, dermographia, etc. In hysterical, neurasthenic and psychesthenic patients without vasomotor or cardiac symptoms all these changes are apt to lie within the high limits of the normal.

In Cheyne-Stokes's respiration Eyster,[14] by means of blood pressure studies, has been able to subdivide the patients into two groups. In one there is a rise of blood pressure during the period of respiratory activity and a fall during apnea; in the other the reverse conditions are true. In each there is a slowing of the pulse with the fall in blood pressure, so that in the first group the slow pulse comes with apnea, while in the second it comes with respiratory activity. The first group is associated with increased intracranial pressure, the second with cardiac and renal disease. These changes in blood pressure are not due solely to the changes in respiratory activity, since different curves are obtained when the Cheyne-Stokes rhythm is imitated by the normal individual.

It has been currently believed that the blood pressure is greatly increased in those working under increased atmospheric pressure. It was supposed that the superficial vessels were compressed and contracted and that there was a superficial anemia with corresponding engorgement of the large trunks of the internal viscera. This was considered to be a factor in some of the disabilities of compressed air workers. Brooks [8] has investigated the systolic and diastolic pressures with the Janeway sphygmomanometer in 75 men working under compressed air (31 lbs. above atmospheric pressure) in the New York tunnels. Pressures were measured before entering, after one to two and one-half hours' work in the compressed air and again after leaving. He obtained the following results:

	mm. of Hg.
Average systolic pressure before entrance,	116.19
" diastolic " " "	91.08
" systolic " in compressed air,	128. 88
" diastolic " " " "	87.68
" systolic " after exit,	112. 76
" diastolic " " "	90.78

These changes are all within the limit of change produced by work under normal atmospheric pressure. As a corollary to these results Brooks states his belief that patients having cardiovascular disease should do as well at high altitudes as at low and that moderate renal or circulatory disease should not disbar men from working under moderate air pressure.

Systolic pressure during pregnancy and the puerperium has been studied by Vogeler.[36] During pregnancy he considers 100 to 150 mm. of Hg. normal. During labor the pressure rises, but after labor any departure from these limits is abnormal. Hypotension (below 90) is significant in estimating the importance of profuse or long-continued hemorrhage. Moderate hypertension (150–180) is not incompatible with the completion of a full-term pregnancy, but marked hypertension (over 180) is always a cause of grave anxiety lest eclampsia supervene. Vogeler believes that persistent hypertension with increasing edema and the development of cerebral symptoms is extremely dangerous and that interference with pregnancy would be the better policy.

Sheppard [30] considers blood pressure in typhoidal perforation and concludes that a rise is not so common as Crile's figures would indicate, but in conjunction with other signs is a valuable aid in diagnosis.

In Addison's disease the blood pressure is very low, 75 to 85 mm. of Hg. in a case of Short.[31] This author believes the pigmentation is also a result of the low blood pressure, for with the vascular relaxation there is an increased function of the pigment forming cells. Treatment in his case with adrenalin and digitalis gave good results for a period of some months, though the case eventually relapsed and died of the disease.

Since carbondioxide baths usually raise the blood pressure in cardiac cases as one form of their good effects, the question has been raised whether or not they are contraindicated in cases of high blood pressure. In two papers, Groedel and Groedel,[17] and Baur,[1] show that high blood pressure is no contra-indication if the baths are used with caution, since in most of these cases there is a very slight or no rise, and in many an actual fall. Bing [4] utters a note of warning against the use of blood pressure determinations in the estimation of the value of hydrotherapeutic procedures, since as shown by him the effect may be to cause changes in the peripheral vessels which influence the readings without changing the actual pressure. So minor changes in blood pressure readings may be of no significance.

Low blood pressures have usually been found in pulmonary tuberculosis. Reitter [27] has investigated the systolic pressure by means of the Gärtner tonometer in renal tuberculosis and finds that here the tension is usually below normal when there is no true nephritis or cardiac hypertrophy. Cases of renal calculus with pyelitis, on the other hand, usually show a normal or high pressure, so hypotension may be said to be suggestive at least of renal tuberculosis as against renal calculus. The cause of the lowered pressure of tuberculosis has been attributed by some to the action of tuberculin. Bauer,[2] however, fails to find any low tension produced in man or rabbits

by injections of Koch's old tuberculin, except when the reaction was positive. Then there was a slight fall due rather to the reaction than to any specific blood pressure lowering substance in the tuberculin.

In chronic Bright's disease Elliott [12] finds a considerable hypertension as contrasted to cases of arterio-sclerosis with normal or slightly elevated blood pressure. In experimental uranium nitrate nephritis in rabbits there is a distinct rise of blood pressure (Brodzki [7]) showing that in some way the renal lesion is responsible for the rise. Since the systolic pressure often remains high in chronic nephritis both under conditions of improvement and deterioration in the patient's condition, it is of importance to know the pulse pressure, for a rise in that is of good prognostic omen, while a fall is of bad omen indicating an increased renal insufficiency (Fellner [15]).

Capps [9] has studied the changes in systolic blood pressure following the withdrawal of pleural and peritoneal fluid. With each there is a moderate fall of pressure followed by a gradual rise. The degree of fall depends rather on the rapidity of withdrawal than on the amount of fluid withdrawn.

The average systolic blood pressure in general paresis Walton [37] finds high as a rule. This is apt to be the result of accompanying cardiac and renal conditions. Excluding these cases, pressure is slightly below normal. The blood pressure has no diagnostic importance in general paresis.

The following quotation from Janeway [22] is a suitable introduction to any discussion of the therapy of high blood pressure. Janeway says, "The height of the blood pressure gives no indication whatever for treatment except along preventive lines. Hypertension is no more to be attacked therapeutically than is a heart murmur. Only those symptoms which point unmistakably to inadequate maintenance of the circulation or to sudden threatening danger give us the signal to interfere." The importance of this view cannot be overestimated. Janeway divides treatment into three divisions, (a) preventive, (b) adjuvant and (c) emergent. Under preventive he suggests rest, milk diet, avoidance of strains, excitement and excessive use of tobacco and alcohol. Digitalis is a valuable adjuvant and should be used at the onset of cardiac insufficiency, and the indications for its use are the same whatever the blood pressure readings. As emergent treatment, Janeway employs nitroglycerin and the nitrites, bleeding or light chloroform narcosis. In severe abdominal pain and headache associated with hypertension, morphine is often efficacious.

Oliver [25] employs somewhat similar treatment. He emphasizes a decrease in the bulk of food and a decrease in the amount of meat eaten. A reduced salt diet is often of use. A milk-vegetable diet is for this reason employed, since not only the sodium chloride used as a condiment is to be reduced but also food with a low salt content must be given. Oliver further recommends the D'Arsonval electric current and electric light baths. Medicinally he uses a morning saline in hot water combined with an intestinal antiseptic as benzolnaphthol, salol, etc., and gives thyroid extract, potassium citrate, the nitrites, iodides, hippurates or benzoates.

Steven [33] divides high pressure cases into two groups, (1) temporary and recurrent form and (2) continuous form. The latter is practically always associated with chronic renal disease and it is the renal condition that is to be treated. The former group is usually the result of errors or excess in diet or wine, constipation or nervous excitement. Treatment consists in removing the cause and a judicious use of aperients and the nitrites.

The effect of amyl nitrite inhalations on the blood pressure of man has been studied by Hewlett.[19] He finds a primary fall in systolic pressure followed quickly by a rise until the pressure passes above the original to fall again to normal in five or six minutes after the inhalation. The diastolic pressure acts similarly but to a less marked degree. With these changes there is an increased heart rate so that the result is to cause the heart to pump more blood and give a more rapid flow through the body under normal conditions. With nitroglycerin the effect on blood pressures was usually slight and inconstant.

Cook [10] points out that many patients still go to operation with the old routine of a cursory auscultation for cardiac murmurs and urine analysis for albumin and sugar, and during operation the general condition of the patient receives rather scant attention by the etherizer, who is usually an inexperienced man. Blood pressure determinations during and before operation, Cook thinks, furnish one of the best means of estimating the cardiovascular condition and determining the institution of appropriate treatment. Cases with high tension stand the added strain of operation as a rule poorly and tend to cardiac dilatation, excessive hemorrhage, vessel rupture or renal affections. If the hypertension receives appropriate preliminary treatment these dangers are minimized. For this Cook prefers sodium nitrite in ½ or 1-gr. tablets. During operation the Trendelenburg position should be avoided, care taken to prevent any asphyxia with the anesthetic, and not more gauze than is absolutely necessary should be crowded into the subdiaphragmatic region. Low tension cases as a rule stand operation well if proper precautions against shock and hemorrhage are taken, but after operation they seem to lack resistance to infection of all kinds. With them the preliminary fasting and purging should be less stringent and nourishing food should be given early. Strychnia in repeated doses of one-fortieth grain for the adult is apparently most beneficial. Blood pressure determinations after operation are of great value as aids in the diagnosis of hemorrhage, shock, infection and cardiac dilatation. In the latter the usual treatment is directed towards raising the tension, when often it is the vasodilators that are needed, not the Trendelenburg position,

abdominal pressure, adrenalin, caffeine and saline transfusion.

According to Hare [18] the physician very often stimulates the tired heart when attention to the peripheral vessels is needed. When there is hypotension atropine, adrenalin and digitalis are indicated to prevent the heart from wasting its energy in pumping blood into a greatly relaxed peripheral vascular channel. On the other hand, with hypertension other treatment is indicated. Hare divides hypertension cases into three groups: (1) those in which persistently high tension is the result of spasm due to prolonged nervous stress combined with certain abuses as to habits of life, food and drink; (2) those in which tension is high because in addition to spasm there is gradually developing, or has already developed, fibroid changes in the vessels; (3) cases in which, after a prolonged period of high tension, there more or less suddenly develops persistent low tension. In (1) and (2) rest in bed, with massage and the nitrites is essential. In (3) rest in bed is needed but vascular stimulants are required. In all the iodides are valuable. If the high tension is the result of spasm, nitroglycerin will do good, otherwise not. This latter fact is frequently not borne in mind by the physician.

Venous blood pressure has been studied extensively by Sewall.[29] For measuring venous pressure he employs a small spring manometer. The arm of the observed individual is held at the level of the angle formed by the top of the fifth left cartilage and the sternum in order to remove gravity effects. A superficial vein is selected with a firm underlying tissue. The spring manometer is held freely in the hand, the pad is pressed down on the vein which is then wiped empty by a stroke of the finger and the pressure is relaxed on the manometer until the blood begins again to flow under the pad at the end of the instrument. The piston is then pressed against the side of its bed with the finger, the instrument is lifted and the pressure read off.

By this means Sewall [29] has made many observations on venous pressure. He finds that local and general exercise raise venous pressure; cold lowers and heat raises it; and there is a respiratory variation corresponding with the respiratory changes in arterial blood pressure. In cases with cardiovascular disease arterial and venous pressure may bear varying relations to each other as follows: (a) the ratio of arterial to venous pressure may be increased; (b) the ratio may be decreased; (c) the ratio remains unchanged but both are abnormally high, and (d) the ratio remains unchanged but both are abnormally low. As yet no great diagnostic importance can be attached to these changes.

At an inquest held in an English city, according to the *Medical Record*, it was stated that there were signs of lead poisoning in the system of a man who had been a heavy drinker. The doctor explained that it was probably due to his having been an early-morning customer at public houses, as a consequence of which he would be served with the beer which had stood in lead pipes all night.

Reports of Societies.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

TWENTY-FIRST ANNUAL MEETING.
HELD AT WASHINGTON, D. C., MAY 7 TO 9, 1907.

(Continued from No. 6, p. 192.)

WEDNESDAY, MAY 8, SECOND DAY.

DRAINAGE TUBE FOR USE AFTER PERINEAL PROSTATECTOMY.

DR. FRANCIS R. HAGNER, of Washington, D. C., presented a metallic drainage tube which he had devised for use after perineal prostatectomy. Rubber tubes often became plugged, necessitating removal. Dr. Hagner's tube was something like the Kemp rectal tube, except that it had four openings. It was made of silver, and was provided with a collar which was stitched to the wound. The tube could be removed, leaving the collar in place, simply by loosening a screw. He had also devised a metallic drainage tube, with a single current, for use after external urethrotomy.

PRESENTATION OF APPLIANCES TO FACILITATE THE MAJOR GENITO-URINARY OPERATIONS.

These, presented by DR. F. TILDEN BROWN, of New York, included a portable folding board, leg rests, a modified clover's crutch, an apparatus for raising the loin during kidney operations, and cushions for the last apparatus.

PRESENTATION OF A NEW MODEL OF THE AUTHOR'S CYSTOSCOPE.

DR. BROWN presented a new model of his catheterizing cystoscope, and also a modification of the Otis observation cystoscope.

OINTMENT DEPOSITOR.

DR. HUGH H. YOUNG, of Baltimore, presented an instrument which he used in making applications of ointments to the posterior urethra. He had found during the past year that the ointment treatment of chronic urethritis, irritability of the prostatic urethra, etc., was very efficacious.

PUS TUBES IN THE MALE.

DR. WILLIAM T. BELFIELD, of Chicago, read this paper. He reviewed the anatomy of the posterior urethra, ejacular ducts, seminal vesicals and vasa deferentia. Prostatic concretions were normal features, because found in every adult male over thirty-five years of age. In later life they were increased with lime salts, and were apt to set up suppuration in the prostatic follicles. The spontaneous epididymitis so common in these patients seemed usually attributable to these concretions. The utricle had a distinct clinical importance, though ignored in all standard works. Only three references to disease of the utricle could be found in the literature. Infection and abscess were frequent. A typical gonorrheal abscess of the utricle was recently seen by himself and Dr. Schmidt, which was opened with the finger-nail, through the rectum. Abscess of the utricle should be opened through the rectum; abscess of the prostate through the perineum. The ejaculatory ducts might open into the utricle. He found four such cases in human subjects. This was natural in some of the lower animals, as the rodents. The gonococcus was rarely found in the seminal tube except during the first few months of a gonorrhea. While the gonococcus reached the posterior urethra in

75% of cases, it invaded the epididymis in only 10% of cases, or 5% of the epididymes. The colon bacillus was a rare inhabitant of the urethra, but a frequent invader of the vesicles. Pus infections of the vesicle, ampulla and epididymis were in large measure independent of the gonococcus. Dr. Belfield then described his operation of opening the vas and applying medication to the seminal tube and vesicle. He had now done the operation 97 times, in 76 cases, both vasa having been injected in 21 cases. Typical cases were reported.

DR. HUGH H. YOUNG, of Baltimore, thought the pathology and treatment of diseases of the ampullæ of the vasa deferentia had received entirely too little attention, and that a great many cases had been put down as chronic vesiculitis which were really chronic ampullitis, if that term might be used. He had used injections of iodoformized oil into the vas in cases of genital tuberculosis, after excising the epididymis, and had obtained good results.

DR. EDWARD MARTIN, of Philadelphia, had never been able to tell by clinical examination whether the greatest inflammation was in the ampulla or the seminal vesicle. He had always hesitated to do the more extensive operation of opening and draining the vesicles, and thought Dr. Belfield had suggested a very good way of relieving the retention. He asked if Dr. Belfield had found any difficulty in entering the vas and keeping the opening patulous; whether he had had any cases of descending infection from the site of operation, and whether he had found cases of obliteration of the vas above his point of opening and between that and the principal site of infection, the base of the bladder. He also asked as to the ultimate disposition of the opening in the vas, whether it was sutured or not and whether obstruction tended to occur afterwards.

DR. FRANCIS R. HAGNER, of Washington, D. C., said that in operating on a case of acute epididymitis together with an acute vesiculitis he had made one injection of argyrol into the vas with marked improvement of the vesiculitis.

DR. LOUIS E. SCHMIDT, of Chicago, had had experience in over 20 cases, in many of which the symptoms suggested a prostatic trouble. He opened the vas, inserted a blunt needle, sewed it in place, and left it in for from one to three weeks, depending on the improvement. Injections of 10 to 20% argyrol were made daily, at first injecting 5 to 10 ccm., later 20 to 30 ccm. at a time. In three cases treated by this method, he had observed them for two or three years and there had been no return of their trouble so far.

DR. E. E. KING, of Toronto, said he had never had the courage to adopt this method of treatment for fear that he might set up a worse condition than the one he was trying to cure. He had used the opsonic treatment in several cases, with encouraging results.

DR. BELFIELD said he had given the subject of stricture of the vas considerable attention. He had never used bougies, but had used silk worm gut, horse hair and brass wire. In only 3 cases had there been a distinct obstruction in the pelvic portion of the vas. Infection had extended downward into the epididymis in one case. The opening in the vas was easily controlled if the operation was done properly. He divided the vas transversely, passed his sutures, and left them loose until he was ready to restore the lumen of the vas, when the threads were simply tightened, drawing the divided ends of the vas together.

THE DIAGNOSIS OF HYPERTROPHY, CANCER AND INFLAMMATORY INDURATION OF THE PROSTATE, AND THE APPLICATION OF PERINEAL PROSTATECTOMY TO THESE CONDITIONS.

DR. HUGH H. YOUNG, of Baltimore, said the question of the operative treatment of carcinoma of the prostate was one of the most important in prostatic surgery. To do anything in the way of a radical cure, an early diagnosis was necessary. During the past year a great many more cases had come into his practice, and he had now carefully tabulated 75 cases. It was interesting to know that none of these patients was under fifty and only one over eighty years of age. The age limits in hypertrophy were different, a good many of those being under fifty and over eighty. The majority of cases of carcinoma were found between sixty and sixty-nine years of age. Nineteen cases had no symptoms longer than one year, 13 between one and two years, 21 between two and three years, 9 between three and four years, 6 between four and five years, 3 over five years, and in 3 cases over ten years. Forty-five cases began with frequency of urination, 28 with difficulty in urination, two with sudden complete retention and one with incontinence. Pain was a much less frequent symptom. Hematuria was the initial symptom in one case. In 72 of the 75 cases the prostate on examination was of a stony hardness. In no case was there no induration at all. In 38 cases the surface was rough or nodular, in 37 the prostate was smooth. The seminal vesicles were involved in 43 cases. During the course of the disease the symptoms differed little from those of hypertrophy. Pain and hematuria were just as frequent, or a little more so, in hypertrophy, and the urinary symptoms were very much the same. In prostatitis the symptoms were distinctly different, there being more sexual disturbance, as loss of sexual power, early ejaculation during intercourse, and often a peculiar burning pain in the deep urethra. A good many showed obstruction of urination, this symptom appearing in 34 out of a series of 358 cases. Eighteen required operation, of which 5 were cases of complete retention. Contraction of the bladder and irritability of the posterior urethra were more frequent in prostatitis. To be of benefit in carcinoma, the diagnosis should be made early. Dr. Young said he was not able to make an early diagnosis in a single case in which a diagnosis of carcinoma was made. Only one of these cases recovered, the others dying of recurrence. In prostatitis the vesicles were involved, and the surface of the prostate was usually more irregular than in carcinoma. In cases of chronic prostatitis in elderly men cystoscopy showed a slight median bar, but never the condition seen in prostatic hypertrophy. In carcinoma the seminal vesicles were involved in the later stages. Cystoscopy in carcinoma showed that the disease rarely reached the bladder directly, but as a rule traveled up behind the prostate into the region of the ampullæ and seminal vesicles. Only in two or three of the cases had the disease involved the bladder from the prostate. In carcinoma there was a marked thickening of the suburethral tissue of the prostate, it was difficult to pass an instrument, on account of stricture of the anterior part of the prostatic urethra, and there was a thickening below the trigone. A highly indurated condition of the prostate in a man over fifty ought to make one suspicious of carcinoma. If on cystoscopy one found a nodular median lobe, and possibly lateral lobes projecting into the bladder, and if on palpating the prostatic urethra with the instrument in it one found no thickening of the front portion of the prostatic urethra, it was probably not carcinoma. If there was stricture in the prostatic urethra, an induration and thickening beneath the prostatic urethra, and a stony hardness of the prostate on rectal examination, one was safe in making a diagnosis of carcinoma. On operation, if the operator was at all suspicious of carcinoma, a small piece should be removed, frozen and examined before proceeding with the operation. If it was cancerous, a complete perineal prostatectomy was done. He was

of the opinion that the prospects of being able to effect a radical cure were better than in carcinoma of the breast, the prostate being more encapsulated than the breast, and the metastases later in their appearance. Radical cure was possible only by an early diagnosis, and in making an early diagnosis, every indurated prostate ought to be suspected. Dr. Young had operated on 22 cases of chronic prostatitis. They were patients distinctly unfavorable, who suffered with marked irritability of the posterior urethra and a certain amount of obstruction, generally associated with a contracture of the badder and hypertrophy of the bladder wall. Several of the cases had had complete retention of urine. Two young men under thirty had to use a catheter, one for twelve years. Five of the cases were operated on by the Bottini operation, with fairly good success, but it seemed if an operation was to be done perineal prostatectomy was much safer than the Bottini operation. It was better to do a cutting operation and remove a good deal of the prostate and leave good drainage for the rest. The cases operated on had had fine results. One of them had since become the father of a boy, and in others sexual powers had been interfered with only a few months. If the operation was carefully done, the power of sexual intercourse and ejaculation would not be interfered with. In one of the cases the incision was carried a little farther and the seminal vesicles drained.

DR. WILLIAM T. BELFIELD, of Chicago, said he had noted what did not seem to be present in Dr. Young's cases of carcinoma of the prostate, early and extensive metastases. The value of any method of treatment would depend on the ultimate results, and those would depend largely on the metastases. He had yet to be convinced that it was ever necessary to operate for chronic prostatitis.

DR. L. BOLTON BANGS, of New York, said primary carcinoma of the prostate was not so rare as it used to be thought to be. Notwithstanding all that Dr. Young had said, there were many cases where it was absolutely impossible to make an early diagnosis. So much depended on the refinement of touch, the temperament of the individual, the determination of relative firmness or hardness, etc. In his experience, the initial symptom was not necessarily hemorrhage.

DR. ARTHUR T. CABOT, of Boston, had found nodularity more often in his cases than Dr. Young had described. He had found tightness of the prostatic urethra a characteristic symptom, and he had also met with a symptom which he had seen mentioned somewhere, and that was severe pain on withdrawing a catheter. Hemorrhage had not been an early symptom in his experience. He agreed with Dr. Young that carcinoma of the prostate remained a local disease longer than in many other locations. He had operated in two cases of chronic prostatitis, but they were very severe cases and in young men. He would try Dr. Belfield's plan.

DR. C. L. GIBSON, of New York, had used Dr. Young's technique in two cases of carcinoma of the prostate, and said he wished to contribute a word as to its efficiency. It was not so formidable an operation as it appeared from the photographs. The only difficulty was the separation from the rectum, which had to be dissected up carefully. He had never used Dr. Young's method of operating for prostatitis, but he had used Alexander's method of doing an external urethrotomy and opening and draining the lateral lobes.

DR. LOUIS E. SCHMIDT, of Chicago, had operated in 3 cases of chronic prostatitis, in which the predominant symptom was pain. A year after the operation the pain was just as bad as before. The urinary symptoms were somewhat improved.

DR. H. M. CHRISTIAN, of Philadelphia, thought the stony hardness of the prostate a most important symptom. He agreed with Dr. Cabot as to nodularity of the prostate. He had noted sciatic pain in some of his cases. He thought the method of palpating the prostatic urethra with the cystoscope in the bladder was the most convincing and most important point. He was inclined to agree with Dr. Belfield that we had hardly reached the point where we were prepared to operate in chronic prostatitis in early adult life.

DR. EDWARD MARTIN, of Philadelphia, said nothing had been said concerning the associated spasm of the vesical sphincter in chronic prostatitis, which could be relieved by over-dilatation. For this purpose he had had an instrument made by which the sphincter could be stretched up to 90 French. Bony metastases might occur before any symptoms of prostatic carcinoma appeared.

DR. JOHN VAN DER POEL, of New York, mentioned two cases of carcinoma of the prostate he had seen recently. One of them was mistaken for sarcoma, on account of its regularity. Metastasis could not be made out in either case. Unfortunately, neither case would permit an operation. He said he would be loth to operate for chronic prostatitis. In none of his cases of prostatectomy had he been able to preserve the sexual function.

DR. EDWARD L. KEYES, JR., said he and his father had been doing a modified Bottini operation in cases of contracture of the neck of the bladder, with fairly good results. It was well worth while to consider the advantage of the instrument mentioned by Dr. Martin for stretching the neck of the bladder in those cases, and thought such a procedure was indicated when in those cases there was residual urine. He asked whether Dr. Young considered that prostatic hypertrophy did really begin to show itself clinically in young persons.

DR. HARVEY G. MUDD, of St. Louis, mentioned the case of an old man past eighty years of age, who had a large, smooth, soft prostate. On doing perineal prostatectomy when the capsule was broken through it was found that they were dealing with a large soft cancer of the prostate.

DR. YOUNG said in closing that he wanted it understood that he did not recommend operation as a routine treatment of chronic prostatitis. He had only operated in 4 cases of chronic prostatisis without obstruction out of about 1,000 cases.

NOTE ON PROSTATECTOMY.

DR. ARTHUR T. CABOT, of Boston, said he wished to speak of the causes which he had seen for failure in prostatectomy. He had had an opportunity to observe the results from both perineal and suprapubic operations. Sometimes portions or flaps of the urethral mucous membrane were left, which later obstructed the mouth of the urethra. This was more apt to follow an operation done from above. In badly infected cases it was advisable to treat the bladder some time before attempting the operation on the prostate.

DR. HUGH H. YOUNG, of Baltimore, had seen cases in which a flap had obstructed the urethra after prostatectomy, and he thought in these cases it was advisable to excise the capsule along with the lobe, using a cautery to prevent hemorrhage. He had never had to remove a prostate piecemeal, and he thought this was because he made the lateral incisions very deep.

DR. L. BOLTON BANGS, of New York, could not agree with Dr. Young that it was always possible to enucleate the prostate and not remove it piece by piece. There were also cases in which it was impossible to remove the prostate through the perineum.

DR. FRANCIS R. HAGNER, of Washington, D. C.,

said his experience agreed with that of Dr. Bangs as to the impossibility of enucleating certain prostates, even when the lateral incisions were made deeply.

DR. JOHN H. CUNNINGHAM, of BOSTON, had done the rapid median operation in 24 cases, in 2 of which there had been obstruction of urination afterwards, due to the fact that sounds had not been passed subsequent to the operation. It was important to keep these cases under observation and pass sounds for a time.

DR. JOHN VAN DER POEL, of New York, mentioned a case where it had been impossible to enucleate the middle lobe, on account of its pedunculated condition, and in order to get it out it was necessary to remove the mucous membrane with it.

DR. HUGH H. YOUNG, of Baltimore, thought that where the mucous membrane was preserved it was never necessary to pass sounds after a perineal prostatectomy. He had met with only one case, in a series of 200 cases, in which there was stricture after operation, and that was in an old man who had a very fibrous median bar, and the urethra was incised in that case.

DR. CABOT said he had two or three times removed several of these vesical outgrowths into the bladder. In one case he had removed four one after another. They were easily hooked out with the scoop used in removing stones. He always explored the vesical neck with his finger before putting in drainage after operation.

(To be continued.)

Book Reviews.

Text-Book of Psychiatry. A psychological study of insanity for practitioners and students. By DR. E. MENDEL, A. O. Professor in the University of Berlin. Authorized translation. Edited and enlarged by WILLIAM C. KRAUSS, M.D., Buffalo, N. Y., President Board of Managers, Buffalo State Hospital for Insane; Medical Superintendent, Providence Retreat for Insane; etc. Philadelphia: F. A. Davis Co.

This, the first English version so far as we are aware of any of Professor Mendel's writings on insanity, is a text-book — rightly called a psychological study of insanity — for students attending clinics and young physicians who are subject to examinations. It is seldom that a book of its size — 300 pages — covers as this does such a wide range of subject and detail without sacrificing clearness and proportion to conciseness. In the process of condensation not only are all subjects that are likely to be of practical value to the student adequately treated, but a surprising amount of matter is included that is principally of interest to the experienced alienist. A helpful feature is the frequent use of example and illustration in the exposition of the subject. Another is the employment of apt terms to express in abbreviated form various manifestations or lines of morbid thought. Equally useful is the assembling of the different varieties or groups of mental disease in which a given condition may occur, — a practice often overlooked in text-books on insanity. These and other features together with the author's disease-pictures which are sufficiently descriptive for the purpose of the work should give the student a good working knowledge of the subject and a sound basis for its further study. As most students and young physicians will have to deal with the emergencies and other temporary conditions of insanity it perhaps matters little that the author restricts dementia precox to a rare variety which in point of frequency (2% to 3% of all cases of insanity observed) approaches the original hebephrenia of Hecker. The special student of psychiatry, however, will be more confused than ever in interpreting the nature of dementia precox to find such a high authority inculcating a conception of this disease which classes as separate and distinct "forms" or symptom-groups several conditions which, according to the modern doctrines of psychiatry, are regarded simply as episodes or phases in a chronic dementing process of not uncommon frequency.

The supplement contains a "guide for the examination of one mentally diseased and for the preparation of the clinical history" which is excellent. It is unique in our language for its comprehensiveness and minuteness of detail. For the Prussian procedures relating to the insane the editor has substituted the New York state laws and commitment form.

With the exception of an occasional crude or ambiguous expression the translation is a satisfactory one and the editor is to be congratulated on so promptly giving to English readers and workers so useful a book for clinical instruction from such an authoritative source.

Green's Encyclopedia and Dictionary of Medicine and Surgery. Vols. III and IV. Chicago: W. T. Keener & Co. 1907.

Volume III of this encyclopedia carries the subject matter practically through the letters E, F and G, and completes nearly one-third of the entire work. In this volume there are more than one hundred articles of less than one thousand words but of more than ten lines, discussing many subjects which might seem deserving of more extended comment, did the limits of the book allow. For example, metabolism, medical ethics, germinal pathology are included in this list. Attention is drawn to the fact that cross references, with which the volumes are liberally supplied, are of much value in making an encyclopedia practical through facilitating immediate reference. With this we are in entire agreement. The contributors to this volume, as to the earlier ones, are an assurance of the accuracy of the statements made.

Volume IV carries the work from the latter part of the letter G through H and a part of I, containing 872 subject headings. The articles are for the most part brief and well illustrate the possibility of concise statement of important facts, a quality which many books, even of this character, fail to attain. Up to this point we heartily commend the work to our readers, a recommendation which we may be assured will not be changed when the succeeding volumes appear.

Medical and Surgical Journal.

THURSDAY, AUGUST 15, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

THE QUESTION OF SPONTANEOUS GENERATION.

AFTER a long period of relative neglect, the subject of so-called spontaneous generation has again been revived through the recent publication of a book by Dr. H. Charlton Bastian, entitled, "The Evolution of Life." (E. P. Dutton & Co.) It will be remembered that some thirty years ago an active controversy went on regarding the origin of living matter in which the chief disputants were Dr. Bastian, Professor Tyndall and M. Pasteur. The controversy was aroused by a book published in 1872 by Bastian, entitled, "The Beginnings of Life," and actively prosecuted for a number of years. Now, for approximately thirty years, however, Dr. Bastian had not again taken up the cudgels in a discussion which had aroused much acrimony until the publication of the book to which we have alluded. Dr. Bastian is now emeritus professor of the principles and practice of medicine in University College, London, and consulting physician to several large hospitals. His professional life has been an active one, and it is evident that it was not through a withdrawal of his views but rather because of stress of other work that he has so long remained silent upon the subject which has always been of extreme interest to the scientific world. He now returns to the fray, reinforced in his position by the investigations of the past years, and at a time when all his adversaries, including Huxley, have passed beyond the reach of controversy.

In the exhaustive work which Bastian has now published he maintains his views, previously expressed, with unaltered firmness. He maintains that the logical point of view is to regard the production of living matter as a continuous series of evolutional results, and that the genesis of living matter is continually going on as it has been for ages past. To this process the general term of "archebiosis" is given. This point of view, Bastian urges, is substantiated by the most recent bacteriological investigation and by the study of various primitive forms of life. Huxley's famous dictum, *omne vivum ex vivo*, influenced by Pasteur's researches, Bastian asserts was not an impartial verdict, and that, as a matter of fact, Pasteur's own inductions have not stood the test of subsequent investigation. It is not possible in the space at our command to enter into the detail of argument which Bastian uses to substantiate his own and to repudiate the claims of his opponents. His general conclusion, however, is that the existence of lower organisms at this time cannot be explained as derivatives from primordial forms which originated in an incalculably remote past. Such an assumption, he holds, is contrary to the general evolutionary hypothesis. He believes, on the contrary, that the present existence of such organisms may be adequately and satisfactorily explained on the hypothesis that organic life in our own time is in the act of being continually evolved from inorganic matter.

It is not to be expected that this view of Bastian, commonly but not altogether properly called spontaneous generation, will be immediately accepted by men of science, but we likewise have no question that in this, as in other supposedly decided questions, renewed agitation will be of benefit and lead ultimately to the exact facts. From the point of view of the practical physician, the matter has a certain added interest. In relation to the contagium of various infectious diseases, it at once becomes of vital importance, not only to avert and find the source of infectious and contagious diseases, but also to search still more diligently into the conditions which render possible the production of the infecting agents. If certain fixed conditions are capable of producing agents of contagion, it forthwith becomes apparent that much of the work of the future lies in studying the conditions under which infection arises, as well as the natural history of the agents themselves. We may surely expect new light on this complex subject during the next fifty years. In the meantime it is well to maintain an open mind.

AMERICAN PHYSICIANS IN GERMANY.

THE kindness shown American physicians by German professors, privat-docents and assistants has been proverbial, but, perhaps, never more

than at the present time. Their clinics are held with open doors, their wards and laboratories are readily accessible, and even paid courses are frequently given to one or more Americans at great personal inconvenience to the instructor. In one clinic four times a week the foreign visitors are invited to a demonstration at which interesting cases are shown and the new lines of research there being carried on are described. The recipients of these courtesies are to a considerable extent individuals whose stay at any one particular clinic is transitory, seldom those who have gone to Europe with the intention of entering upon original research either abroad or at home. For the German teacher it is, therefore, all "give," but no "take."

If German medical hospitality is proverbial, American appreciation of German medicine is widespread. And this is evidenced on all public occasions and in our literature. To a considerable ex[illegible]his is known in Germany, but the mere pre[illegible]ce of a large body of American students in their midst exemplifies our admiration rather than our gratitude.

It not uncommonly occurs, however, that Americans, while attending German clinics, appear in quite another light than they would desire. We refer to their habit of "just dropping into a clinic," without first asking permission. We are convinced that this is from ignorance of German university customs and from the wish to occasion no inconvenience to the instructor. But it is not generally appreciated in this country that the salaries of university teachers in Germany come from two sources — the university or government and the individual student. It is easy to imagine the sensations which might arise in an instructor's mind when, looking up to crowded benches, he sees a group of unknown foreigners who have neither asked beforehand the privilege of being present nor expect afterwards to present their acknowledgments. Occasionally the matter is even more aggravating, because the popular teacher (and the Americans always find such a one out) may see his own students, who have paid him to lecture to them, turned away because their places have been filled by medical travelers from many lands. As to the feelings of a German student on such an occasion, perhaps it is as well not to enter. The reputation which is afforded a professor by a crowded clinic is not so great as might appear, for in the eye of the University the number of registered students and not the visitors count. It is true that the evident interest and the wrapped attention which the stranger gives the lecturer must be an inspiration and a reward far greater than money alone, but this does not take away from the American the obligation invariably to ask permission to attend a German clinic. Such a request is easily made and it is optional with the professor in granting it, whether he allows any encroachment upon his time.

REPORT OF STATE BOARD OF INSANITY.

THE eighth annual report of the Massachusetts State Board of Insanity covers a period relative to general matters for the year ending Sept. 30, 1906. The entire number of persons under supervision on October 1 was 12,388, or 274 more than the previous year. The larger proportion of these come under the category of the insane, being in the somewhat startling proportion of one insane patient to every 295 persons of the estimated population of the state. The statistics seem to show that there has been a slow but steady increase in the number of insane, but in the estimation of such statistics it should always be borne in mind that methods of classification are continually changing and that the condition itself depends largely upon definition. There has, however, been a decline in the number of patients treated at public institutions, a possible reason for which is given in the following statement: "It is probable that the present general prosperity tends to diminish the inflow of patients into institutions by furnishing work which in dull times might not be available for an indifferent class of labor, and, by affording a larger and steadier income to the bread-winner of the family, increasing the ability to care for dependents."

The statements which follow regarding commitments, first cases of insanity, nativity and other matters of statistical significance should be carefully read by those interested in the great problem which mental disease presents. It is evident, if our classifications can be made uniform, and if some definite conception of what is to be included under the heading of insanity be established, statistical reports will become of increasing value from year to year. This volume is an excellent example of a carefully prepared public report.

MEDICAL NOTES.

YELLOW FEVER. — It is reported that an outbreak of yellow fever has appeared in the American garrison at Cienfuegos. Up to August 13, eleven cases had appeared, but it is not likely that the disease will spread to any extent.

Professor von Leyden's Successor. — It is stated that Professor H. His, a son of the anatomist, will succeed Professor von Leyden at the University of Berlin in the chair of special pathology and therapeutics.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, August 7, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 24, scarlatina 21, typhoid fever 16, measles 38, tuberculosis 68, smallpox 0, leprosy 0.

The death-rate of the reported deaths for the week ending August 7, 1907, was 20.19.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Aug. 10, 1907, was 222, against 237 the corresponding week of last year, showing a decrease of 15 deaths and making the death-rate for the week 18.99. Of this number 128 were males and 94 were females; 218 were white and 4 colored; 161 were born in the United States, 64 in foreign countries and 7 unknown; 53 were of American parentage, 146 of foreign parentage and 23 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 30 cases and 5 deaths; scarlatina, 19 cases and 0 deaths; typhoid fever, 19 cases and 0 deaths; measles, 33 cases and 3 deaths; tuberculosis, 48 cases and 14 deaths; smallpox, 0 case and 0 death. The deaths from pneumonia were 14, whooping cough 1, heart disease 27, bronchitis 0 and marasmus 8. There were 22 deaths from violent causes. The number of children who died under one year was 56; the number under five years, 24. The number of persons who died over sixty years of age was 34. The deaths in public institutions were 78.

Day Camp for Tuberculosis. — It is reported that 140 persons are enrolled as patients of the day camp for tuberculosis in Mattapan near Boston. Upwards of twenty are on the waiting list. From these facts it appears that this charity is demonstrating its usefulness and is appreciated by an increasing number. Most of the patients go from the tenement sections of Boston, South Boston, East Boston and Chelsea, in spite of the time taken in travel and often the excessive heat. Records already show marked improvement in many cases, and it is not to be questioned that the plan begun tentatively two years ago has proved a most valuable adjunct to the other methods in the treatment of the disease. Visitors to the camp are welcome at any time.

NEW YORK.

Roof Playgrounds and Gymnasiums. — Among the American delegates to the second International Congress of School Hygiene, just held in London, was Dr. Luther H. Gulick, supervisor of physical training in the New York public schools. He states that the Congress was deeply interested in the roof playgrounds and gymnasiums of New York. In his opinion, America leads the world in the matter of the physical training of school children, but in Europe more attention has as yet been paid to medical supervision. This, he believes, will not be the case long, as it is now being recognized that a complete knowledge of the child's physical as well as mental condition is essential before his education is undertaken.

Mortality during July. — The weekly reports of the Health Department show that during the month of July the mortality in the city represented an annual death rate of 18.71, as against 16.94 in June and 19.33 in July, 1906. Among the diseases in which there was a diminished fatality were the following: The weekly average of deaths from measles declined from 28.5 in June to 27.75 in July; the weekly average from scarlet fever, from 26.75 to 17.75; from diphtheria and croup, from 38.75 to 32.25; from influenza from 4.75 to 0.75; from epidemic cerebrospinal meningitis, from 11.75 to 10; from pulmonary tuberculosis, from 159.5 to 150.25; from pneumonia, from 83.5 to 43.75; from broncho-pneumonia, from 97.5 to 77.25; from cancer, from 66.25 to 58.5; from apoplexy, congestion and softening of the brain, from 49 to 41.5; and from organic heart diseases, from 132.75 to 117.5. Among the diseases in which there was an augmented mortality, were the following: The weekly average of deaths from typhoid fever increased from 8.75 to 10.5; from malarial fevers, from 1 to 1.75; from acute bronchitis, from 13.5 to 14.25; from diarrheal diseases, from 67.25 to 323.75; from diarrheals under five years of age, from 60.75 to 313.75; from Bright's disease and acute nephritis, from 96.5 to 103; and from cirrhosis of the liver, from 19.75 to 25.5. The corrected death rate, excluding non-residents and infants under one week old, was 17.67. During the first part of July the health of the city was exceptionally good.

In the week ending July 6 the death rate was only 16.13, the lowest point reached since the first week of November of last year; while in the corresponding week of 1906 the death-rate was 19.19. Later in the month, however, there was a rapid increase in the deaths from diarrheal diseases in infants and young children, and in the week ending July 27 there were 550 deaths from this cause in children under five, as against 373 in the corresponding week of last year. The generally recognized association of broncho-pneumonia with summer diarrhea is also shown in the statistics; for while in the corresponding week of 1906 there were but 38 deaths reported from this disease, in the week ending July 27, 1907, these amounted to 85.

Obituary.

SIR WILLIAM TENNANT GAIRDNER.

The recent death of Sir William Tennant Gairdner removes another distinguished physician of the older generation. Dr. Gairdner was born in Edinburgh in 1824, and therefore had lived to the ripe age of eighty-three. His father had been a distinguished practitioner in Edinburgh, and it was not unnatural, therefore, that the son should follow in the same profession. He was graduated in medicine in 1845, while still under twenty-one, and shortly after graduation returned to Edinburgh as resident physician of the Royal Infirmary. In 1848 he became pathologist to the Infirmary, in 1850 a fellow of the Royal College of Physicians of Edinburgh, and in 1853 a physician to the wards of the Infirmary and lecturer on the practice of medicine. In 1862 he received the appointment of professor of medicine in the University of Glasgow, at the age of thirty-eight. He thereafter devoted nearly forty years to medical practice and research in the west of Scotland, and during that period numbered among his colleagues many men of great prominence, among whom were Lister, William Ramsey and John Caird. His interest in public health began while still at the Edinburgh Infirmary, and in 1863 the Corporation of Glasgow appointed him their first officer of health, a position which he held for nine years. Sir William was the first president of the Glasgow Pathological and Clinical Society, founded in 1873. He later made an unsuccessful application for the chair of medicine in Edinburgh, vacant by the death of Laycock. Although unsuccessful in attaining this object of his ambition, he received the honorary degree of LL.D. from Edinburgh University in 1883, and from that time on various other honors were bestowed upon him, among others knighthood in the year 1898. Some years before his death Gairdner had become the victim of the Stokes-Adams syndrome with the development of a periodic slow pulse which ultimately became permanent. His death, on the 28th of June, was sudden. Gairdner was one of that large class of physicians for which England and Scotland have become famous, who combined much learning with good fellowship and rare affability of manner.

Current Literature.

Medical Record.
July 20, 1907.

1. Lockwood discusses gastroptosis and its management. Out of 2,000 patients he has found 351 suffering from gastroptosis. The disease runs a typical and characteristic course, and can be divided into stages. It begins with subnutrition and nervousness, and occurs especially in persons with an acute costal angle. In such persons prophylactic treatment should be instituted. In the first stage there is gastroptosis alone without any symptoms. In the second temporary atony sets in with intermittent symptoms, consisting of gas in stomach, heartburn and distress after eating. Later follow permanent and continuous symptoms. Gastritis is not an etiological factor, neither is tight-lacing. In fact, a straight-front corset gives support and is of value. Intermittent atony is brought on by mental and physical strain. Fermentation has been proven by the author's experiments not to occur in atonic stomachs, in which food is perfectly digested as a rule. High gastric acidity exists and prevents fermentation. Distress depends on the amount of gas and quantity of food. Neurasthenia and constipation result. Flushing of the colon will bring away strings of mucus. Restricted diet brings on subnutrition and makes the patient worse. Examination of stomach contents shows a top layer of clear liquid and a lower one of digested food. Inflation is valuable to aid in diagnosis. Treatment of permanent atony involves rest in bed for four weeks with entire absence of worry and of society, with a trained nurse in charge; hot baths and spinal douches, massage and a very nutritious diet, excluding fruits and red meats, given in six small meals a day. Bromide is an indispensable remedy. Under such treatment weight increases, the curvature of the stomach rises, and a cure is complete after six weeks or so. Prophylactic treatment consists of teaching the patient not to undergo strains, mental or physical, and keeping up the general condition.

3. Dardel says that the treatment of syphilis by the use of sulphur waters does not pretend to cure alone, but forms a very valuable auxiliary treatment which may be combined with a course of mercurial treatment and will help greatly in the absorption, action and elimination of the drug. The cure is indicated at any period of the disease, since nutrition suffers at all stages. Patients suffering from arterio-sclerosis, or liver trouble, and those that are highly nervous should not undergo an active sulphur cure. It is especially indicated in those that take mercury badly, or can tolerate but a small dose of it, and in those in whom therapeutic action of mercury is not easily obtained. Also in cases of great destruction of tissue, or severe infections in feeble and worn-out patients. Again in lesions of the nervous system, ulcerative lesions that threaten great destruction to the organs affected, and other such lesions in which there is no time to lose. The treatment strengthens the patient and enables him to take more mercury and assimilate it better. The sulphur of the water forms alkaline sulphides. Some are oxidized to hyposulphites and sulphites, but the most of it forms hydrogen sulphide, which is eliminated by the lungs and skin. It has a general tonic and exciting action and

liberates mercurial compounds stored up in the system. The author describes the use of sulphur waters externally and internally at Aix-les-Bains, where massage combined with douching is an important factor in the treatment. Marloiz water is also drunk.

4. Keating refers to cases that are really incipient, giving no marked tuberculous symptoms and no physical signs. The facts elicited from physical examination of the chest should be regarded as only confirmatory of the diagnosis. Important factors are family history, occupation, spitting of small amounts of blood, chilly sensations, very slight fever, an indefinite history of night sweats, loss of weight, constipation, clammy hands, a red line on the gums and shallow breathing. Respiration may be slightly jerking, with harsh inspiration. The pulse is accelerated. As to the treatment the author does not favor the use of tuberculin. He recommends beginning treatment with six weeks' rest in bed, in the open air as far as possible. Three meals a day should be taken and milk and eggs used besides. The most useful drugs are arsenic and nux vomica. No cough mixtures should be used. The best sedative is milk and eggs taken before going to rest for the night. Morphine is the only remedy for profuse hemorrhage.

NEW YORK MEDICAL JOURNAL.

JULY 20, 1907.

6. Kennedy, J. C. *Pelvic Tumors in Little Girls.*
7. Bryant, B. L. *The Rational Treatment of Nervous Diseases.*
8. Chandler, G. *The Treatment of Acute General Peritonitis.*

1. Clark and Atwood report a series of cases of rare types of nervous disease. The first is a case of Landouzy-Déjerine myopathy or the facio-scapulo-humeral type of progressive muscular dystrophy. the atrophy first appearing in the face. This case is especially noteworthy in that the disease was apparently congenital; no other congenital case is found in the literature. Other conditions described are peroneal dystrophy, Thomsen's disease, multiple enchondroma, acute poliomyelitis in an adult, and two cases of anterior poliomyelitis with exaggerated knee-jerk. [F. W. 1. Bevan has gradually increased his use of nitrous oxid as an anesthetic, now employing it in a large proportion of his general surgical cases, including operations upon the gall-bladder, kidney, stomach and appendix. He maintains that it is the safest anesthetic as well as the most agreeable to take. Administered with air, anesthesia of a half hour to an hour can be secured. The expense involved in its use could be greatly reduced in hospitals if apparatus for its production were placed in operating rooms. It is proposed that a committee on anesthetics be appointed to study and report each year's progress in this field of work.

2. Mitchell advocates the more general use of local anesthesia. When first introduced local anesthesia fell into dispute on account of poisoning due to too strong solutions of cocain. Recent methods, however, with weaker solutions, the injection of nerve trunks, and the addition of adrenalin to solutions under the danger of cocain poisoning are slight. The author's experience includes a wide range of operations done under local anesthesia. In operating upon inguinal and femoral hernias he feels that general narcosis is never necessary. It is important to understand the relative sensibilities of different tissues. The skin being thoroughly anesthetized, there is little sensation in the subcutaneous tissues and in muscles so long as blood vessels, large nerve trunks and connective tissue bundles are avoided. Periosteum is exquisitely sensitive, but when this has been cocainized the bone beneath has no sensation, as is shown by a case of trephining which is described. The dura was incised and the brain cortex touched without sensation. The parietal peritoneum is sensitive but the visceral peritoneum and the viscera are not. Clamping and cauterizing the appendix give no sensation, but pulling on the mesentery causes pain referred to the epigastrium, and nausea. The liver and kidney have been incised without pain. In preparing solutions tablets of cocain .05 gm. and adrenalin .00016 gm. sterilized, are dissolved in sterile salt solutin. Such solutions containing 1% of cocain are used for nerve blocking, and .1% solutions are used for ordinary infiltration.

3. Lusk calls attention to the importance of a correct understanding by physicians of the food requirements of the body, especially the proteid and fuel requirements. He points out the false claims made for the advertised breakfast foods, the merits of which lie in their flavors and not in their exaggerated nutritious value. The various malt extracts are also mentioned as well as the peptone preparations, which consist chiefly of albumoses which are liable to cause diarrhea, and the liquid peptonoids which contain a considerable quantity of alcohol and only about 25 gm. of proteid to the pint bottle. It is said that many patients have died of proteid starvation through the ill-advised administration of these preparations. If used as a flavor or stimulant their limitations should be fully recognized.

4. Allen describes his work in attempting to produce a vaccine for tuberculosis from bacilli contained in sputum. The process is given in outline. The object in obtaining the bacilli from sputum is double. In the first place it is thought to be possible that the bacilli from the patient under treatment may be so specialized as to have special properties adapting them for use in immunizing the particular patient from whom they are obtained. In the second place it is thought that bacilli directly from the human body may possess properties which are lost in artificial cultivation. The preparations obtained contains, besides tubercle bacilli, pus corpuscles and other bacteria. The bacilli other than the tubercle bacillus may be of value in effecting immunity against secondary infections.

5. Wentworth suggests as a possible cause of infantile atrophy, a defective correlation of the several digestive organs, stomach, intestines, pancreas and liver. This hypothesis is based on the discovery of Bayliss and Starling of the substance called by them "secretin," originating

in the small intestine and passing from it through the blood to the pancreas, and to some extent to the liver, which organs are stimulated by it to secrete. He reports experiments on cats made to ascertain the effect on the pancreatic secretion of the secretin obtained by Bayliss and Starling's method from the cadavers of atrophic, newborn and other infants. The tabulated results show that the material obtained from the intestines of atrophic infants possessed little or no power to stimulate the flow of pancreatic juice in the cat, indicating either a lesser strength or quantity of secretin present. The secretin from well-nourished infants and children, on the other hand, always caused activation of the cat's pancreas. He thinks it very unlikely that the diminution of secretin can be due to inanition, as suitable food restores the functions rapidly before the general marasmus of the infant has been bettered. He has also experimented to ascertain as far as possible how much it can be due to digestive disturbances, etc., and while his investigation is not yet finished, he is inclined to offer the following hypothesis as the result of the research thus far to explain the cause of infantile atrophy. The digestive functions of the very young infant are not activated because it does not receive the only food capable of activating them, viz., mother's milk. This leads the stomach to secrete an inadequate gastric juice, and the duodenum is therefore not stimulated to form normal secretin. The defective secretin insufficiently stimulates the pancreatic secretion, and leads probably to as yet unstudied disorders of the function of the gut lower down. What renders the milk specific in this way is now engaging his attention and he hopes to be able to answer it in the future. It is possible that it is due to some hitherto overlooked specific substances or to certain hitherto disregarded factors in chemical composition.

15. Laplace advocates in the treatment of erysipelas superficial scarification of the reddened area and of the skin for an inch or so beyond its border, followed by applications of ice-cold bichloride of mercury acidified by the addition of 5 parts in 1,000 of hydrochloric acid.

BULLETIN OF THE JOHNS HOPKINS HOSPITAL.

MAY, 1907.

1. *WATTS, S. H. *The Suture of Blood Vessels. Implantation and Transplantation of Vessels and Organs.*
2. MUMFORD, J. G. *Boston Medicine One Hundred Years Ago and a Notable Physician of the Last Century.*
3. HELMHOLZ, H. F. *An Adenoma of Island of Langerhans.*

1. Watts's article begins with an exhaustive historical review of work done upon the suture of blood vessels, from the lateral sutures of wounded veins and arteries, the circular sutures of divided vessels and various anastomoses, to the implantation and transplantation of arteries and veins and the replantation and transplantation of organs. The results reported are too numerous for detailed mention in this abstract. They include many failures, and a general want of certainty of results remains even in the most recent work. Many successes, however, are striking, particularly those attained in the transplantation of organs, notably of kidneys, with maintenance of function. Watts then reports in detail the results of his own experiments, undertaken to determine in what proportion of sutures of vessels success may be expected. Working with dogs he operated 31 times upon vessels of the neck with perfect results in 28; of 12 operations upon the femoral vessels only 2 were entirely successful, the failures being attributed to the impossibility of keeping the wounds properly dressed. It is concluded that, when aseptic technic is good, completely divided vessels can be sutured with almost uniform success.

13. WATSON, A. *Hydatid Disease in Australia.*

1. Moynihan gives his results in 334 operative cases of non-malignant stomach disease, dividing them into the following groups: (1) Perforating ulcer, 27 cases with 18 recoveries and 9 deaths. (2) Recurrent hemorrhage, 33 cases, of which 27 recovered and 6 died. (3) Miscellaneous cases 248, with but 2 deaths. (4) Hour-glass stomach. 26 cases, with 4 deaths. The perforation of an ulcer of the stomach never comes unannounced. In many of the patients the symptoms have persisted for months, and in some they have been of greater severity in the weeks or days preceding the rupture of the ulcer. When perforation occurs there is a sudden agonizing pain, but there is neither shock nor collapse as a rule. The pulse at the first is not rapid and the abdominal muscles may not be rigid. Moynihan has always found exquisite tenderness of the skin, the least stroking of the surface with the finger being resented. He further insists that the onset of those symptoms, formerly considered as necessary to a diagnosis,—collapse, abdominal distension, rapidity and smallness of pulse — should not be allowed to develop. A diagnosis can be made from the history of ulcer, the sudden onset and continuance of intolerable pain, restriction of thoracic movements, surface tenderness, and abdominal rigidity, or restriction of the normally free abdominal movements. Early operation in these cases, with infolding of the ulcer, is always indicated. Unless the ulcer is so near the pylorus as to cause obstruction, or unless a second ulcer can be seen in the vicinity of the pylorus, gastroenterostomy is not necessary. Drainage is necessary only in the late cases. When used it should be by a supra-pubic wound with the patient kept in the sitting posture. In the cases in which hemorrhage necessitated operation, this was always from a chronic ulcer. It is the repetition of hemorrhage in increasing quantity at decreasing intervals that is the only cause demanding operation for its instant relief. Infolding of the ulcer with gastroenterostomy is the safest and best procedure in such cases. In men 50% of the bleeding ulcers are in the duodenum, while in women 66.6% are in the stomach. In performing the posterior no-loop gastroenterostomy the normal jejunal direction should be observed and maintained. To make the anastomosis always in one direction, Moynihan feels to be wrong.

2. The presence of abdominal or pelvic pain in patients with ovarian cysts usually indicates either secondary changes in the cysts, involving some sensitive nearby structure, or the presence of some other condition independent of the cyst which may cause pain. The principal causes of pain arising from ovarian cysts are traction or twisting of the pedicle, or traction on the parietal peritoneum from adhesions. These findings are based on 10 cases operated on by Sampson under local anesthesia.

4. Graham reports a case in which six years after amputation of the breast for scirrhous cancer, multiple metastatic foci were found in the viscera at autopsy, there having been absolutely no clinical symptoms leading to a suspicion of their presence. Dense bands of adult fibrous tissue intersected the tumor area; in some places there was a complete capsule around the whole mass.

8. Kanavel believes that in some cases of leontiasis ossea operation should be done either to relieve cerebral compression, or encroachment upon the orbital and nasal cavities. Obstruction of the blood supply and operations for cosmetic purposes may be considered. [W. C. Q.]

2. Mayo reports 5 certain and 4 probable cases of diverticulitis of the sigmoid. These cases all occur during the age when cancer is common (over forty years) and are often confounded with it. The clinical diagnosis cannot be positively made, but one should always consider this condition in a case presenting left-sided pain low in the abdomen coming in spells and associated with constipation. The rather sudden formation of a mass, following such an attack of pain, would make the diagnosis yet more probable. Blood in the stools is an important sign in favor of cancer. The surgical treatment depends upon the condition present. Localized suppurative cases must be treated by free drainage. If, in conjunction with the infectious process acute obstruction of the bowel develops, a temporary artificial anus should be made. If a considerable tumor is present and the symptoms do not show a tendency to disappear it is better to make a primary resection of the affected bowel before abscess and fistula supervene. The milder cases which tend to spontaneous recovery do not suggest operative treatment.

3. Roberts advises the use of elastic constriction in the treatment of delayed union of fractures. He uses the bandage more or less continuously and of a firmness just sufficient to produce a slight bluish venous congestion at and below the seat of fracture.

6. In an experience based on over 375 operations for goiter Mayo has seen but one case develop tetany and that only in the slightest degree. Some myxedema and other evidences of hypothyroidism have been present in a few cases before operation and in none has this condition been increased. In 5 cases the hoarseness from the effects of pressure has been increased by operation. The careful preservation of the posterior capsule of the thyroid gland protects against many of the dangers of thyroidectomy.

9. Out of 416 cases of primary operation for cancer of the breast at the Massachusetts General Hospital from 1894 to 1903 inclusive, 376 were traced to a conclusive end result at an average period of eight years after operation. Sixty-four cases were alive and well and 7 died without recurrence over three years after the operation. Counting in the operative mortality, there were 320 attempts at radical cure, 67 of which (20.9%) were successful. During this period palliative operations were performed on 56 patients (15%) and 52 cases were discharged untreated. Cases in which the tumor was ulcerated or was adherent to the skin or to the chest wall, and cases in which the axillary glands were palpably enlarged, gave notably less promising results than when these conditions did not exist. No case with palpably enlarged cancerous glands above the clavicle, and no case of cancer of both breasts, was cured. Medullary carcinoma was more grave than that of the scirrhous type, and adeno-carcinoma and colloid were relatively of a far less malignant type. The duration of the disease and the age of the patient exerted little influence on the prognosis. Extensive operations with wide removal of skin gave the greatest freedom from local recurrence. Removal of the pectoralis minor appeared to be of slight significance. Incomplete operations on early cases yielded better results than extensive operations on cases which were well advanced. Recurrence in the scar occurred in less than one-half of the cases; internal metastasis was most frequent in the lungs, mediastium, axillary and supra clavicular glands, the liver and the spine. Seventeen out of 88 cases (19%) of those passing the three-year limit without evidence of recurrence, showed recurrence later, and 4 cases developed recurrence six years or more after the operation.

18. Crile makes the following statements: (1) The operative technic of cancer of the neck has reached the point of development which enables the surgeon to operate each case individually, with sole reference to excising every particle of malignant growth, and in no way recognizing the so-called types of operation such as Whiteheads, Kocher's etc. (2) The loss of blood plays an important rôle in the remote as well as in the immediate results. (3) The immediate use of the x-ray applied upon the naked wound is useful. (4) The only tissue which must be respected to the extent of determining the breadth of the excision of the growth is the common or internal carotid artery; the sterno-mastoids — one or both — the sterno-thyroid, sterno-hyoid and platysma muscles, either on one or on both sides, need not be considered as of functional importance in weighing the chance for a successful eradication of a malignant growth. On the same ground, neither the internal nor the external jugular on one or on both sides need be considered, nor a unilateral excision of the vagus, of the phrenic or of the hypoglossal nerves. (5) The creation of a granulation tissue barrier across the base of the neck under cocain anesthesia, by the packing of iodoform gauze in the deep planes of the neck prior to operation, protects the mediastinum with almost certainty. (6) The immediate operative risk has fallen to a minimum. (7) The chances for final cures compare favorably with those of cancer of the breast. Of the patients operated previous to 1900 31% have no recurrence, while of those operated between 1900 and 1904, 40% have no recurrence.

19. Freeman emphasizes the fact that when the nerves are badly involved in ischemic paralysis, and show no signs of prompt recovery, they should he liberated from compression early, before hopeless degenerative changes set in. [W. C. Q.]

7. WEBER, F. P. *Multiple Hereditary Developmental Angiomata (Telangiectases) of the Skin and Mucous Membranes Associated with Recurring Hemorrhages.*

4. Forsyth experimented on fowls fed on semi-raw meat over a long period with a view to confirm or disprove Watson's statements that this diet will cause changes of

importance in the thyroid gland. He concludes as a result of his investigations that there are no changes or hypertrophy of the thyroid; and that there are no bony changes providing there is lime enough in the diet. In none of the birds was there any indication of gout, but there was an unusual amount of colloid in the pituitary gland. His results cast considerable doubt on Watson's experiments.

6. Clarke and Sutherland report results of a study of the effect of tuberculin (T. R.) on the positive and negative phases of the opsonic index. They believe that by rapidly increasing doses it is possible to raise the index for a considerable period. They have made 492 observations of the index in 32 tuberculous cases, but do not pretend to define the value of tuberculin in treatment, or of the opsonic index as a guide to that treatment.

1. Williamson has made a study of the so-called "vibrating sensation" which is felt when a vibrating tuning fork is placed, foot down, on a subcutaneous bony prominence in many parts of the body. This sensation varies in health and in disease and its presence or absence may be an important diagnostic sign. He concluded that it is a delicate test for slight impairment of sensation in early tabes, in slight peripheral neuritis, and often in diabetes mellitus. In diseases strictly limited to the motor structures the vibrating sensation is not lost even at an advanced stage of the disease. If it is found to be lost it means that the disease is affecting the sensory structures also. In cases of paraplegia from spinal caries, and occasionally in spinal syphilis the loss of the vibrating feeling may be the only objective symptom of affection of sensation. In hemi-anesthesia due to organic disease the vibrating sensation is felt when the foot of the vibrating tuning fork is placed on the edge of the sternum on the side of tactile anesthesia, while in hysterical hemi-anesthesia the reverse is the case.

4. Wilson believes in treating the various spasmodic neuroses, such as spasmodic torticollis, not by surgery but by developing a rhythmical movement the reverse of the one constituting the neurosis, and curing it by this means. He gives the details of this treatment in torticollis and various trade spasms.

2. Croner and Seligmann conducted a series of experiments on dogs and human beings showing that, contrary to previous reports, arsenic can be found in the stools and urine for considerable periods after the injection of atoxyl. In dogs the subcutaneous injection of 1.5 gm. for three consecutive days caused a marked arsenic reaction eighty hours afterwards. Tests on human beings gave the same results.

4. Proskauer reports the clinical history and pathological findings of a very severe typhoid in a young child. The immediate cause of death was a purulent peritonitis, which bacteriologically showed streptococci and for which no perforation of a typhoid ulcer or mesenteric gland could be found. The stomach, duodenum and jujenum were thickly strewn with typical ulcers, which were younger anatomically than those in the cecum. Culturally the ulcers showed the paratyphoid bacillus B, and the serum reaction was positive to this organism and negative to the typhoid bacillus. Such marked ulcerations in the stomach and upper intestine are exceedingly rare.

6. Kamp was able in connection with a case of myotonia congenita to trace the disease back through four generations, and concludes that the disease is inherited through both the male and female, but in the male line it is quickly extinguished, while in the female it persists for a long time. If the disease stops in one member of a family, the descendants are free from it.

[L. G. M.]

Tetany. CHOVSTEK (*Wien Med. Wochenschr., No.* 23) says that all those factors which previously have been considered as being the etiological cause, are merely exciting causes. In individuals affected with tetany, the onset of menstruation, an angina, or as the author has seen, the injection of tuberculin, is sufficient to excite an attack. The specific cause of the reaction in tetanic individuals is a constitutional one, and is probably associated with a functional disturbance of the parathyroid glands.

[L. G. M.]

Herpes in Cerebro-spinal Meningitis. EINHORN (*Wien Med. Wochenschr., No* 23) finds that herpes occurs in over half of the cases of epidemic cerebrospinal meningitis, and that it has the following characteristics: it appears commonly from the third to the sixth day of the disease, and persists for a considerable period, rarely as long as fourteen days. The vesicles are unusually numerous and thickly sown, with fresh vesicles appearing alongside of old crusted lesions. The site of the eruption is often atypical as in the gluteal region, the lobe of the ear, finger, or scalp. The involution of the vesicles is considerably longer than that of the herpes in ordinary febrile diseases, and often leaves small scars.

[L. G. M.]

Miscellany.

PHYSICAL CONDITION OF WEST POINT CADETS.

A WRITER in the *Medical Record*, having made some severe strictures on the physical condition of the cadets at the United States Military Academy at West Point, Lieut.-Col. Charles Moore Gandy, chief surgeon at the Academy, has taken sharp issue with the author of the communication. The latter claimed that the cadets were so overtrained, worked so hard, and got so little sleep, that their constitutions were so run down and they were so physically unfit that they were unable to resist infections or adverse conditions which were harmless to others. When he saw the corps he was painfully impressed by their bad condition, which, he believed, fully accounted for their lowered vitality and resistance. The great majority, he said, had thin, drawn features and very slender figures, suggesting emaciation.

They seemed to have been "worked down" or "trained" to a condition which the progressive element in the medical profession now recognized as one of dangerous exhaustion with little surplus for emergencies. In support of his claim he stated that the newspapers had reported that a large number of West Point cadets were made ill by their stay at the Jamestown Exposition and that two or three contracted typhoid fever, while a large number of cadets of other schools went to the Exposition and were quartered amidst the same unsanitary conditions, and yet no reports of such sickness were reported about these. Furthermore, he contended that even in athletics the West Pointers did not excel, while in science or letters the Academy's graduates were seldom heard from. Colonel Gandy states that it is true that three of the corps contracted typhoid fever at Jamestown, but this was not due at all to the unsanitary condition of their quarters. Two of them took the disease from eating ice cream, aganist which the cadets had been warned, and the third from drinking water from a penny-in-the slot device, which was supposed to furnish water, but which an investigation showed to be connected with a common water main. The general health of the West Pointers, he says, was as good as or better than that of the other cadets there, and if any infectious disease occurred among the latter it was hardly like that it would be reported, for the reason that immediately after leaving Jamestown the boys scattered to their homes in all parts of the country. In the year ending June 30, when he made his annual report, there was not a single case of contagious disease in the Academy, and for more than eleven years there had not been a death among the cadets there. He then denies the fact that the cadets were overtrained and claims that the corps is the finest body of young men in the country, physically, mentally and morally. He thinks the world has heard something of Ulysses S. Grant and Robert E. Lee. At the present time, Colonel Goethals is in charge of the work on the Panama Canal. His immediate aids are West Pointers, and it was to the graduates of the Academy that the country had to look for the carrying on of this great undertaking, after various others had given it up.

THE GYNECOLOGICAL STOMACH.

Women of all classes, when subject to diseases of the genital tract, tend to be dyspeptic as well. The two conditions are often results of the same cause, whilst too often, possibly, treatment aggravates both. That nutrition is not independent of the influence of some compound or some nerve agency in the genital organs there can be no doubt, but what that compound or agency precisely may be science has not as yet revealed to us. Hence, gynecologists are often taunted about their ill success in the treatment of dysmenorrhœa, chronic ophoritis, anorexia nervosa and allied disorders more or less intimately associated with dyspepsia as a more or less marked complication. On the other hand, surgery has triumphed where definite, objective lesions can be removed. It need hardly be said that we refer to ovariotomy and hysterectomy. Yet are there no objective lesions in any of the chronic cases, where stomach-aches, flatulence, vomiting or anorexia are so marked as complications? Are these gastric lesions due purely to lutein, of which we know but little, to vaso-motor changes somewhere, or to our own mismanagement combined with the patient's stupidity and hypochondria? Experience shows that there may be very definite lesions, so definite, indeed, that they ought to be diagnosable. Over twenty years since, Howitz, of Copenhagen, pointed out that gastric pains and dyspepsia after abdominal sections and peritonitis are not rarely caused by adhesions, especially omental. Operators sometimes find the transverse colon so much dragged upon by omental adhesions as to assume the form of a letter V, the point coming close to the bladder. The stomach itself is occasionally dragged downwards in the same manner. Dr. Cerné, of Rouen, discussed the gynecological stomach at the Congrès National de Gynécologie, held last April in Algiers. He admitted that too much had been talked about dyspepsia in ladies with a metritic diathesis, curable by treatment at inland watering places. He insisted, however, that cases are to be met with where a genital lesion is the origin and direct cause of gastric troubles. In enteroptosis, and even in many cases where the parietes are normal, the stomach comes down very low when the patient stands up, but it can be pushed up to its natural level by the hand with the greatest ease. Cerné carefully examined two patients where the stomach could not be replaced, for it was fixed by an adhesion down to one iliac fossa. Both patients were subject to disease of the uterine appendages, and, in Cerné's opinion, the stomach, or, at least, the omentum, adhered to the diseased structures. Other gynecologists have, we understand, met with adhesions of this kind. Hence, where there is a distinct history of old pelvic inflammation, verified by exploration of the genital tract, dyspepsia and other gastric disturbances may imply something more definable and more manageable than a pure neurosis. — *British Medical Journal.*

IMMUNIZATION AND THE PROPHET OF FRESH AIR.

Of the gospel of immunization we need only say that it is a dream, which, however beautiful, is still very far from fulfillment. It cannot be denied, however, that, even in its present inchoate stage of evolution, it has certain advantages. The pity is that so far, while its benefits are positive from the practitioner's point of view, they are often more or less problematic from that of the patient. But it cannot be said that the temper of mind to which the system gives rise in those who follow — or perhaps it might be more correct to say which gives rise to the system — is one that makes for the progress of practical

medicine, that is to say, for the deliverance of mankind from the majority of the ailments from which it suffers. The Pharisee of science looks down on the mere physician or surgeon, giving thanks that he is not even as this publican of practice. Yet what the people ask for is the bread of cure, or, at any rate, relief, and from the laboratory they too often get a stone, occasionally even a serpent.

As for the other prophet, who foretells that the medicine bottles on surgery shelves will be replaced by sunlight and fresh air, the practitioner will probably be inclined to ask where he can get a sufficient and constant supply of these valuable therapeutic agents. The wholesale prescription of these things to poor folk "in populous city pent" is as "extraordinary" as any of those of the ancient doctor who is made the object of cheap ridicule. "Simple living" is by no means easy, except to rich people who have nothing else to do; and that otiose phrase "suitable diet" must sound like a bitter jest to poor starving folk who have to feed themselves and their children on what they can get — too often out of the gutter. — *Practitioner.*

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED JULY 31, 1907.

BANKS, C. E., surgeon. Leave of absence granted Surgeon Banks for one month from June 20, 1907, amended to read twenty-eight days only. July 26, 1907.

SMITH, A. C., surgeon. Directed to proceed to Wheeling, W. Va., for special temporary duty, upon completion of which to rejoin his station at Pittsburg. July 25, 1907.

FRICK, L. D., passed assistant surgeon. Granted leave of absence for seven days from July 22, 1907, under paragraph 191, Service regulations. July 22, 1907.

GOLDBERGER, JOSEPH, passed assistant surgeon. Directed to proceed to Brownsville, Tex., and other places in that portion of the state, for special temporary duty, upon completion of which to rejoin his station in Washington, D. C. July 26, 1907.

MCCOY, G. W., passed assistant surgeon. Directed to proceed to Brownsville, Tex., and other places in that portion of the state, for special temporary duty, upon completion of which to rejoin his station in Washington, D. C. July 26, 1907.

WARREN, B. S., passed assistant surgeon. Relieved from duty at Boston, Mass., and directed to proceed to Chicago, Ill., reporting to the medical officer in command for duty and assignment to quarters. July 25, 1907.

TRASK, J. W., assistant surgeon. Detailed as recorder of board for completion examination of applicants for entrance to the service, vice Joseph Goldberger, relieved. July 29, 1907.

OLSEN, E. T., assistant surgeon. Granted leave of absence for seven days from July 26, 1907, under paragraph 191, Service Regulations.

OLSEN, E. T., assistant surgeon. Granted extension leave of absence for seven days from August 2, 1907. July 26, 1907.

STILES, CH. W., Chief Division of Zoölogy, Hygienic Laboratory. Detailed to represent the service at the Seventh International Zoölogical Congress, to be held in Boston, Mass., August 19–23, 1907. July 25, 1907.

BRINCKERHOFF, W. R., Director Leprosy Investigation Station, Hawaii. Detailed to represent the service at the Sixth International Dermatological Congress in New York, N. Y., September 9–14, 1907. July 24, 1907.

SPOHN, A. E., acting assistant surgeon. Granted leave of absence for thirty days from July 1, 1907, and excused for a further period of two months from the expiration thereof, without pay. July 29, 1907.

TOWNSEND, F., acting assistant surgeon. Granted seven days' leave of absence from July 29, 1907. July 29, 1907.

TOWNSEND, W., acting assistant surgeon. Granted extension leave of absence for seven days. July 28, 1907.

MACDOWELL, W. F., pharmacist. Granted leave of absence for fifteen days from August 1, 1907. July 29, 1907.

BOARD CONVENED.

A board of medical officers was convened to meet at Chicago, Ill., for the purpose of making a physical examination of an Inspector of Immigrants. Detail for the Board: Surgeon G. B. Young, Chairman; Acting-Assistant Surgeon William Kimmet; Acting-Assistant Surgeon J. J. Gerkin, Recorder. July 25, 1907.

BOOKS AND PAMPHLETS RECEIVED.

The Essential Similarity of Innocent and Malignant Tumours. A Study of Tumour Growth. By Charles W. Cathcart, M.A., M.B., C.M. (Edin.), F.R.C.S. (Eng. and Edin.). Illustrated. New York: William Wood & Co. 1907.

The Seventeenth Annual Report of the Eye, Ear, Nose and Throat Hospital, 1906, New Orleans, La.

Treasury Department, Public Health and Marine-Hospital Service of the United States. Hygienic Laboratory. Bulletin No. 43.

Surgical Instruments in Greek and Roman Times. By John Stewart Milne, M.A., M.D., Aberd. Illustrated. Oxford. 1907.

Morris's Human Anatomy. A Complete Systematic Treatise by English and American Authors. Edited by Henry Morris, M.A. and M. B. Lond., F.R.C.S. Eng., and J. Playfair McMurrich, A.M., Ph.D. Fourth edition, revised and enlarged. Illustrated. In five parts, Parts III, IV and V. Philadelphia: P. Blakiston's Son & Co. 1907.

Materia Medica and Pharmacy. By Reynold Webb Wilcox, M.A., M.D., LL.D. Seventh edition, revised. Philadelphia: P. Blakiston's Son & Co. 1907.

Surgery, Its Principle and Practice. By various authors. Edited by William Williams Keen, M.D., LL.D. Vol. II. Illustrated. Philadelphia and London: W. B. Saunders Co. 1907.

Leprosy as Seen by the Hawaiian Practitioner. By Philip R. Waughop, M.D. Reprint.

Massage in Sprains, Bruises, and Dislocations. By Douglas Graham, M.D. Reprint.

TORTICOLLIS.

THE RESULTS OF THE TREATMENT OF CASES OF ACQUIRED AND CONGENITAL MUSCULAR TORTICOLLIS AT THE BOSTON CHILDREN'S HOSPITAL, SINCE 1879.*

BY E. H. BRADFORD, M.D.,
Consulting Surgeon, Boston City Hospital; Senior Surgeon, Boston Children's Hospital; Professor of Orthopedics, Harvard Medical School,
AND
JAMES WARREN SEVER, M.D.,
Junior Visiting Surgeon, Boston Children's Hospital.

THE object of this paper is not to consider the subject of torticollis as a whole, but to present the conclusions in regard to the treatment of torticollis as justified by the experience obtained at the Children's Hospital in the last twenty-eight years. In this paper the term "torticollis" will be applied as referring to that deviation of the head which results from the contraction chiefly of the sternocleidomastoid. The term "torticollis" is, of course, equally applicable to other forms of deviation of the head, namely, that resulting from the reflex spasm in caries of the spine, that resulting from muscular irritation, from the presence of inflamed glands, that from irritation following arthritis of the vertebral articulations, and that resulting from a lack of balance of the muscles following general nervous disorder, but the subject here presented will be limited to a consideration of the methods of treatment of the ordinary torticollis due to the contraction of certain muscles of which the most important is the sternocleidomastoid.

FIG. 1. Torticollis. Right. McDermott, age four and three-quarter years. Date of admission, May 26, 1888. Date of discharge July 13, 1888. Duration, fall at one year. torticollis began one year later. Contraction of right sternomastoid and anterior edge of trapezius. Operation, June 2, open incision, division of sternomastoid and fascia. Buckminster-Brown apparatus.

These cases of wry neck have been due to many causes, the principal one being congenital, the others being caused by the usual rheumatic, traumatic and post-febrile conditions, such as

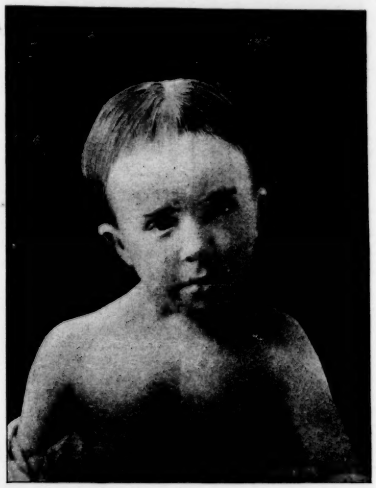

FIG. 2. Torticollis. Right. Howard, age four. Date of admission, Feb, 11, 1895. Date of discharge, April 15, 1895. Duration, two years. Cause, unknown. Operation, Feb. 14, 1895. Dead.

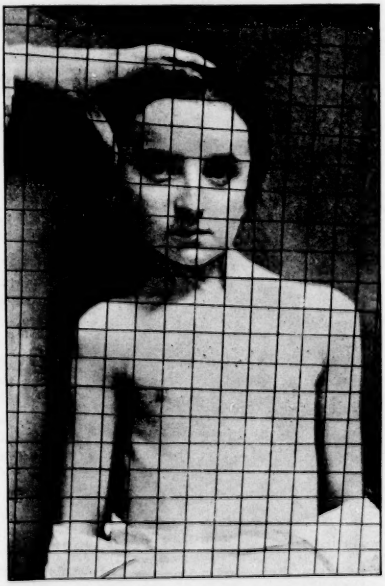

FIG. 3. Torticollis. Left. O'Connor, age eleven. Date of admission, Sept. 3, 1896. Date of discharge, Sept. 29, 1896. Duration since two years of age. No cause. Operation Sept. 5. Fascia and probably both congenital insertions of muscles divided. Traction. Plaster.

*Presented before the American Orthopedic Association, at Washington, May 9, 1907.

typhoid, measles, influenza and scarlet fever. There have been a number of cases of torticollis, but not of the true muscular type, due to tuberculosis, of the cervical vertebræ. These, however, have not been considered in this paper.

We intend to show by this report that muscular torticollis in children from two to twelve years of age is easily cured by appropriate methods; that the result is immediate, that no post-operative gymnastics are needed so far as the cure of the deformity itself is concerned, that simple resection of the two origins of the muscle is all that need be done, and that only rarely need the Scalenii be divided; that the simple transverse incision is the best, and causes the least deformity in the resulting scar; that it is not necessary to remove the entire muscle, as has been done, and that the after-treatment is simple, and of not long duration.

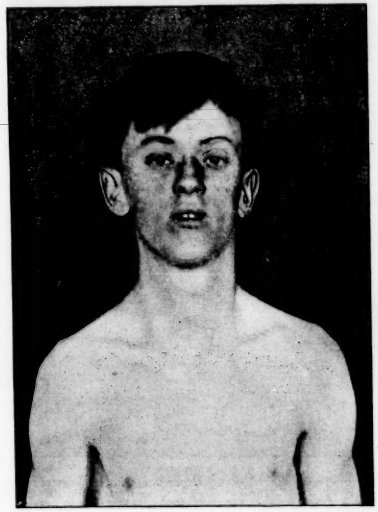

Fig. 4. Torticollis. Right. Driscoll, age five. Date of admission Aug. 28, 1896. Date of discharge, Sept. 3, 1896. Duration, three years. Since birth. Operation, Aug. 28, incision, myotomy, plaster.

Fig. 5. Before operation.

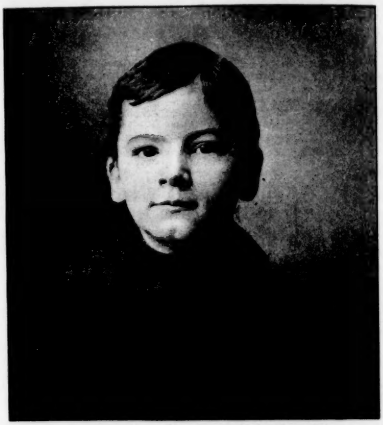

Fig. 6. After operation.

Fig. 7. Torticollis. Right. Carew, age eleven and one half. Date of admission, Feb. 15, 1900. Date of discharge, Feb. 28, 1900. Duration, since birth. Operation, Feb. 20, incision, myotomy. Buckminster-Brown brace.

We are able to report, however, one case, a child a day old, which presented torticollis due to a partial rupture of the sternocleidomastoid of one side, the result of manipulation at birth.

Fig. 8.

Whether this is a common cause of torticollis is a subject which will require the presentation of other facts than those the writers have at their command.

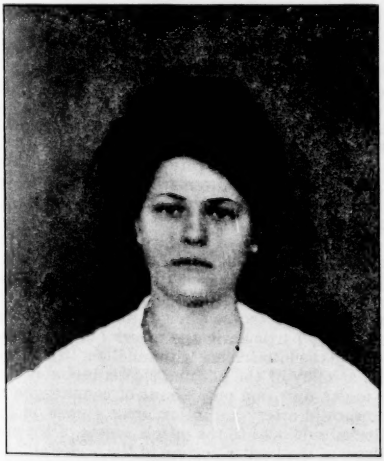

Fig. 9. Torticollis. Left. Carmel, age ten. Date of admission, Sept. 5, 1900. Date of discharge, Sept. 17, 1900. Duration, three years following measles. Operation, Sept. 11. Incision, myotomy, plaster.

ETIOLOGY.

In considering the etiology of the cases of torticollis occurring at the Children's Hospital since 1879 a number of them may be easily accounted for by various traumatic or inflammatory causes. These, however, form but a small part of the total number of cases.

In looking over Table No. 1, it may be seen that those cases which have had a congenital origin form by far the largest number individually.

TABLE NO. 1.

Fig. 10. Torticollis. Left. Clark, seven years, eleven months. Date of admission, Aug. 15, 1902. Date of discharge, Aug 21, 1902. Duration, last two years. Operation, Aug. 18. Incision, myotomy with plaster cuirass.

It will not be necessary to consider further these cases from an etiological point of view, with the exception of those of the congenital type.

Congenital cases. — The usual history in these cases has been that either of a deformity existing at birth, or of a gradually increasing deformity since birth. In none of these cases was there any history of hematoma or instrumental delivery.

There have been so many opinions expressed and causes assigned by various writers as to the cause of congenital torticollis, that it seems wise to review them briefly.

In looking over the great mass of literature on this subject we find that no definite conclusions have yet been reached. The theory of a hematoma alone as a cause has been disproved by Whitman and others, and Witzel has shown by experiments on animals that the artificial production of a hematoma is not followed by contraction of the muscle, either transitory or permanent.

Heredity is to be considered, but is not infallible.

Three of our cases occurred in the same family in successive children.

Diffenbach, Jeannel, Pfeiffer, Fischer and Jachimstal in defense of their theories all cite cases of hereditary torticollis.

The co-existence of other congenital malformations is to be considered as a cause also, such as clubfeet, hands, congenital dislocation of the hip, etc. In none of our series of cases was there any accompanying deformity.

Nervous origin. — Nélaton, Golding Bird, Gallavardin and Savy think that the cause may be sought in a lesion of the central nervous system, and cite a case with autopsy where there was found atrophy of the anterior horns of the spinal cord in the upper cervical region. They think that it may be analogous to infantile paralysis.

FIG. 11. Showing after-treatment with Buckminster-Brown brace.

However, the most plausible and reasonable theory which has yet been advanced is that of Josserand and Vianny, who advocate the *ischemique théorie.*

By a series of autopsies on cases of congenital torticollis in babies, with careful dissection of the sternocleidomastoid muscle with its blood supply followed by injection experiments on the arteries they have shown that the sternal head receives normally the smallest amount of blood furnished to any other portion of the muscle. With the head flexed and rotated in the position it would normally resume " in utero " the arterial supply is much diminished, or wholly cut off, owing to pressure on the sternomastoid middle artery, by the surrounding parts, and the proximity of the thyroid cartilage. This artery is a small branch from the superior thyroid artery, and is the sole source of supply to the sternal head of the sternomastoid muscle.

The deformity then is due to a markedly diminished blood supply, resulting in a degeneration of the muscle fibers, with subsequent sclerosis and contraction.

Facial asymmetry. — The question of facial asymmetry has not been covered as yet, and there are several points of interest to be considered in connection with it. Taken in order these are as follows:

FIG. 12. Three sisters. Posterior view.

1. Causes of facial asymmetry.
2. Is it present at birth in congenital cases of torticollis?
3. How long may a case go without operation before the facial asymmetry becomes permanent, even after operation?
4. Is it wise to operate upon a case of long standing torticollis, with marked facial asymmetry which may result in a cure of the wry neck, but cannot cure a facial deformity?

1. " Asymmetry of the face is ascribed to the gravitation of the blood to the more dependent side, to muscular tension, to pressure and retarded development of the vessels and nerves on the side of the concavity; to tension of the soft parts, particularly the muscles of the sound side and the interference with function." (Young.) The atrophy of the affected side is probably due to faulty nutrition on account of compression of the carotid artery and other great vessels on the affected side, and to the misplacement of the epiphyses of the basilar portion of the occipital bone and the effect of the weight of the skull on the other cranial and facial bones. This latter theory probably explains the osseous changes in the face and asymmetry of the skull.

2. In most cases of congenital torticollis there is a facial asymmetry existing at birth.

3. A number of our cases were of eight and even ten years' duration, before operation, but examinations at present show practically no asymmetry or atrophy. It is probably safe to say that all

cases should be operated upon between two and ten years of age, if permanent deformity is to be prevented.

4. In adults with torticollis of long duration, presenting marked atrophy and asymmetry, it becomes a question for the patient to decide after having the situation fully explained to him. The asymmetry will probably not clear up, and the atrophy may become more noticeable.

PATHOLOGY.

There were no opportunities in our series of cases to verify the pathological condition in the cases of congenital origin, but as these conditions have been pretty well worked out by others we will simply summarize them briefly.

It is usually the sternal head which is affected. This presents on examination an interstitial degenerative myositis. It has never presented the characteristics of hemorrhage with muscular rupture.

FIG. 13. Three sisters. Anterior view.

The affected area is usually found entirely deprived of muscular fibers, with few exceptions presenting a waxy, hyaline condition. What few muscular fibers may be left show a disappearance of their striæ. This condition is constant in children from two to ten. It is also found in any part where the vascular supply is interfered with, as in the ischemic paralysis of Volkman, too long use of the Esmarch bandage, too tight bandaging following immobilizing fractures of the arm, lesions of the great vessels, exposure to excessive cold, causing a slowing down or stopping of the arterial circulation. Histologically, these conditions are similar to those which exist in torticollis.

THE METHODS OF TREATMENT.

These may be enumerated as a non-operative method, muscular stretching, and stimulation; and an operative method, by subcutaneous tenotomy, or open incision.

The non-operative method. — In the cases which have come under this inquiry, a few have previously been treated by non-operative methods; one for several months at a western institution where the treatment consisted of a partial suspension massage and manipulation; in the second case the method was partially applied for some time by domestic nursing. Nothing can be said in favor of this method of treatment as it is manifestly irrational and unscientific. In all typical cases of contraction of the sternocleidomastoid muscle, the rational treatment, therefore, may be considered to be the operative method.

Operative method. — In the early experience of one of the writers, both as hospital interne and later in the early years of his practice as an orthopedic surgeon, the accepted method was by subcutaneous tenotomy. It was considered advisable to divide freely with a small tenotome both insertions of the sternocleidomastoid. One of the writers has performed this operation in two cases and would record his opinion that while the method is capable of giving satisfactory results and diminishes the danger of sepsis and does away with the possibility of a scar, yet the disadvantages of the method are so evident that no conscientious surgeon can recommend that method of operation. This will be readily seen by any one who has performed this operation by open incision and who is familiar with the anatomy of the sternocleidomastoid muscle.

The operation to be thorough will consist of an open incision thoroughly dividing the sternocleidomastoid. There has been some discussion among various writers on the subject as to the proper place of incision of the sternocleidomastoid; whether this should be divided at its insertion, the mastoid process; at its origin on the sternum and clavicle, or in its middle. There are disadvantages in the incision in each of these three points. These can be formulated as follows:

(*a*) The muscle at its insertion at the mastoid process can be readily reached; it can be stripped and separated well from its bony attachment without danger of dividing or wounding the internal jugular.

FIG. 14. Fixation apparatus in bed. After operation.

(*b*) The operation is readily performed and the resulting scar is in a position where it will not be noticeable.

(*c*) The disadvantages of the division of the muscles at the mastoid process are such, it would seem to the writers, as to prevent its adoption in preference to that of the division of the muscle at its origin on the clavicle and sternum.

(*d*) The chief disadvantage of the division of the muscle at the mastoid process is that the muscle at its insertion has a broad attachment and may be looked upon as a surgical aphorism that it is preferable in operating to use incisions which will divide the least amount of tissue. One of the writers has performed the division at the mastoid process in three cases; the results have been excellent, and the method is one which is of value in the hands of competent surgeons, but it does not seem to the writers to have any advantages which justify its adoption.

The division of the sternocleidomastoid at its middle has been advocated by a few surgeons, with the understanding that by this means there is a greater immunity from the possibility of a relapse. The separation of the divided muscle will be greater in its middle than at its ends. The skin incision can be made in the direction of the force of the muscle and in the fold of the neck, and no great danger of a disfiguring scar need be entertained. The muscle at this point, however, is thick, the carotid artery and vein lying close to

FIG. 15. Case in which scalenus anticus was divided.

it, and for this reason the operation requires an unnecessary amount of care through an increased amount of risk.

The division of the muscle at its origin on the clavicle and sternum has the advantage of attacking the muscle where it is most superficial, the most easily reached, with the least dissection. It is for this reason that the writers would unquestionably place their preference for this point as the point for the muscular division in the treatment of torticollis.

It is advisable to take certain precautions to gain the best possible results. The question of scar is one which is of importance. A disfiguring scar upon the neck is, of course, a matter of some moment, and in one case operated upon by one of the writers a small keloid developed, which became a noticeable blemish. In a few other instances the union was not by first intention and a scar followed lasting through childhood. As a rule, however, the operation can be done with a minimum danger of any disfiguring scar. The surgeon, however, should bear this in mind and take unusual pains to prevent the scar and to secure the healing by first intention. It is desirable to plan in such a way that the scar will come just above or just below the clavicle, and that it will be parallel to the clavicle, it being manifestly easier that the skin incision should be made directly on the clavicle. In order to insure the proper position of the scar it is advisable to pull the skin up slightly before incising it. The skin can be divided without any risk if this is done, and it can be arranged that the scar should fall at a point where it will be least noticeable. The skin incision should be free, reaching from the middle of the sternum to at least one-third the length of the clavicle. The incision should be through the skin, subcutaneous tissue, as well as the external fascia, which includes fibers of the platysma. A director should then be inserted, passing it underneath the fibrinous attachment of the sternal end of the sternomastoid muscle and the muscle freely divided, cutting down on to the director which protects the deeper vessels. The director should then be inserted, passing it well under the clavicular attachment of the muscle, and the muscle divided in the same way.

An inexperienced surgeon performing this operation for the first time is apt to be disturbed at

FIG. 16. Buckminster-Brown brace. After operation.

the size of the gap which follows, the retraction of the muscle, and also the apparent depth of the resulting hole. This need, however, occasion no alarm. It is essential that the whole of the muscle should be divided and that the muscular division should be made half an inch above the insertion. After the incision is made in the skin and the retracting pressure removed, the incision will be found to have its center just below the clavicle. This may be regarded as the point of selection, although it may be regarded as neces-

sary to divide the whole of the muscle, including the fascia which covers it, and any fibrinous bands which are lying in the course of the muscle. In order to be sure that everything is divided it is advisable for the surgeon to pass his gloved finger into the wound in order to feel if anything remains undivided. The surgeon should not, however, attempt to divide the deep cervical fascia which is entirely free from the sterno-cleidomastoid and which, lying directly over the internal jugular, should be spared. One of the writers wishes to record an error made in violating this caution, where a division of the deep fascia was performed in an excess of zeal from the desire to prevent the persistence of any possible contraction. The incision wounded the internal

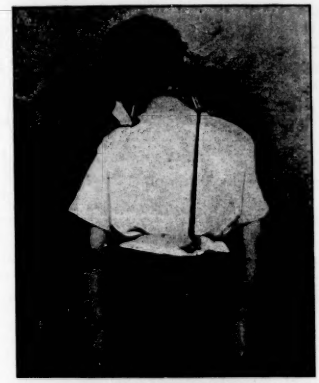

Fig. 17. Posterior view.

jugular and it was necessary to tie that vein, an operation which was both vexatious and dangerous. Fortunately no untoward result followed.

After the muscle is completely divided at both insertions, the surgeon or his assistant should take the patient's head in both hands and, having the shoulders held firm, the head should be twisted into an over-corrected position, and in this way all contractions in other minor muscles stretched.

One of the writers in one case was led to divide the scalenus anticus, but in the usual cases, in children at least, such an operation is entirely unnecessary.

If the operation is properly done no vessels are to be tied and the wound should be carefully closed. It it desirable not to pack the wound nor to leave drains in, in order to insure the absence of a scar. It is needless to say that complete asepsis is essential and that it can be readily secured by the employment of ordinary precautions. Although a cavity is left by the operation which would seem to require drainage, in the cases observed by the writers this has occasioned no trouble as the healing has taken place with the absorption of the blood clot.

Various ways are employed in dressing the wound from the ordinary dry dressing to sealing the wound with a tincture of benzoin. The writers are of the opinion that it is advisable to protect the wound with great care, not only from any septic invasion, but also from any friction. There is no great danger of wound gaping; and it is perfectly safe to close it with catgut sutures, but tension sutures should also be applied. The wound should be covered either with silver foil, or gelatin foil in order to prevent the possibility of rubbing the dry dressing; if that is not done the wound should be dressed the day following the operation.

After-treatment. — At the Children's Hospital two methods of fixation of the head following operation have been practised, both having been successful, and the writers have at various times preferred one and later the other manner of fixation.

If the child after an operation is placed upon a frame and the corrected position of the head maintained by three straps of adhesive plaster (see plate), one along the cheek of the elevated side, passing under the chin and stretching to a cord which hangs over the side of the bed, the chin can be held in an over-corrected position, provided a counter force is exerted by a strap of adhesive plaster passing upward over the opposite cheek, and a third strap passing under the patient's head, also connected with a weight, holds the plane of the face in a corrected position. These three straps can be arranged in a way to cause no

Fig. 18. Showing post-operative corrective apparatus.

discomfort. They permit the dressing of the wound if that is necessary, and, secured by sand bags at both sides of the head, furnish adequate fixation of the head in a corrected position.

In the earlier operations this was the method employed in all cases, but later the advantages of plaster of Paris as a means of fixation seemed manifest, namely, that the irksomeness of con-

finement to the bed is avoided for the patient. Considerable care must be exercised, however, in the application of the plaster of Paris bandages. In the first place the bandage must be applied in such a way that the head is securely held in an over-corrected position, the chin pointing to the opposite side to that which it held before, the plane of the face turned in an opposite direction from that which was held previously, and the ear on the contracted side, which was previously

FIG. 19. Showing post-operative corrective apparatus.

advanced, should be secured in a position more posteriorly. The mastoid process on the affected side should be as far away from the clavicle as possible. It is also important that the plaster of Paris bandage should not rub upon the wound. A window can be cut in the plaster so that the wound can be dressed or inspected.

In the application of the plaster bandage it is desirable that the upper part of the thorax be kept down, which, before the operation, had been raised. If the bandage is properly applied it causes no discomfort, but it can be readily seen that an improperly applied bandage would demand speedy removal.

Where the surgeon is perfectly sure of his technique, and a comfortable bandage is applied, it should be worn without change for a month, after which it can be renewed or left unchanged; but in case of the removal of the bandage some form of retention apparatus should be worn for at least three months following the operation.

Of the various apparatus which have been recommended the writers have found the wire collar, a modification of that introduced by Buckminster-Brown, the simplest and most efficient. In place of this, however, a leather collar, including the neck and also the upper part of the thorax, can be used. It is advisable that over-correction should be maintained for at least three months, after which the head may be gradually freed from its support and massage employed if desirable. As a rule, however, massage is not necessary.

These technical details, although tedious, are perhaps of some importance as they lead to the establishment of satisfactory results which have been obtained at the clinic at the Children's Hospital. It has been somewhat of a surprise to read in many of the journals of the dangers of relapse following the operation for torticollis. In order to determine this, the writers have examined the records of the Children's Hospital, going back twenty-eight years. The cases that were investigated were not all operated on by the writers, but by the writers and their colleagues. No classification is made of the names of the operators, but the method of operation and the technique employed have been substantially the same by the various surgeons performing the operation.

The number of cases investigated was 90; replies were received from 62 cases. The records of such cases as were not heard from were obtained in the hospital, and a note made of their condition at their last visit. As these cases were chiefly the ordinary hospital cases, the after treatment being carried out in the out-patient department, which includes no better care than what is furnished in most out-patient departments, and when it is recorded that recurrence took place in only two cases, and that in one no benefit was considered to be derived from the operation, by the parents, it may be considered that the operation is one which promises

FIG. 20. Showing contraction of sternomastoid muscle.

with ordinary care and after-treatment perfect results.

It is essential that the operation should be carefully done. It is also essential that the after-treatment should be thoroughly carried out. Neglect of either of these two factors would be followed by failure or partial success, but with attention and thoroughness the certainty of cure may be guaranteed.

RESULTS OF TREATMENT.

FIG. 21. Showing contraction of sternomastoid muscle.

There were two cases in which there was a second operation owing to a recurrence of the deformity at intervals of four years in each case. This recurrence was due probably to two causes, namely, lack of completeness of the operation, and insufficient attention to after-treatment.

Showing adhesive strap for over-correction in bed. Post-operative.

The recurrence, however, in but two of the cases traced, answers well for the routine carried out at the hospital, and the skill of the operators. One of these cases was of the congenital type, and one was due to instrumental delivery. Since the second operation there has been no further difficulty, and the results on one of these cases may be seen by referring to picture No. 1.

Post cards were sent to each one of the cases in the series, asking for the present condition of the case, how long a brace or any other apparatus was worn following the operation, and requesting the patient to report to the hospital if the distance from Boston was not prohibitive.

Replies were received from 62 cases, 12 were not heard from, and 18 reported for examination and photographs. The replies received were intelligent and answered the questions asked, and the tabulated results may be seen in Table No. 2.

Oldest operated,	12 years
Youngest operated,	2 years

1. M. B. Girl, age eight. Right torticollis — duration since birth — no cause determined. Labor normal. No marked facial atrophy or asymmetry.

Operation, November, 1889. Open incision — both heads of sternomastoid divided. Plaster cuirass.

2. B. B. Girl, age six. Left torticollis — duration since birth — no cause determined. Labor normal. Operation, November, 1889. Myotomy. Plaster.

3. B. B. Girl, age five. Right torticollis — duration since birth — moderately contracted. No marked atrophy or facial asymmetry. Operation, November, 1889. Myotomy with open incision. Plaster. See group photos 12 and 13.

The three cases cited above are most interesting in that they occurred in successive children — all girls — in the same family. There is no family history of any similar previous condition, and there was a normal labor in each case.

Showing line of incision in skin.

The mother writes that the operations "were successful in every way." This was seventeen years after operation.

4. M. Van K. Age ten. Girl. Double torticollis — duration since birth. No further history obtainable. At two years of age she was operated upon in Michigan. Just what was done at that time could not be ascertained. There was a greater degree of contraction on the left side, as compared with the right. The head was thrown forward, and the shoulders elevated. There were no cervical ribs as sometimes occurs in these cases.

Operation, October, 1903. Myotomy with open incision on the left.

Result. — Apparatus. Buckminster-Brown brace worn six months. April 5, 1906. Father writes from Michigan that the operation was a success, and that the head and shoulders are quite straight.

5. N. McD. Girl, age four and three quarters. Torticollis, right. Duration two and one-half years following a fall. Torticollis noticed soon after. Operation, June, 1888. Open incision. Sternomastoid and fascia divided. Plaster for four weeks — followed by Buckminster-Brown brace for four months.

Result. — February, 1907, head in good position deep depression in the right neck, no facial asymmetry, motion all normal. See photo No. 1.

6. H. Boy, age four. Torticollis, right. Duration two years — cause unknown. Considerable tipping of the head to the right with rotation. Marked atrophy of the right face and asymmetry.

Operation. — February, 1895. Open incision, myotomy. This boy died in the hospital later from the measles. The picture is shown to illustrate the atrophy and facial asymmetry. Photo No. 2.

7. O. C. Girl, age eleven. Torticollis, left. Duration nine years, probably congenital.

Operation. — September, 1896. Open incision, myotomy and fasciotomy.

Result. — One year later head straight. Splint omitted. This case has not been heard from since. Photo No. 3 illustrates also the thread screen to show deviation.

8. Wm. D. Boy, age five. Torticollis, right. Duration since birth. No cause assigned. Congenital. Marked contraction of the right sternomastoid muscle.

Operation. — August, 1896. Open incision, myotomy — plaster.

Result. — February, 1907. No facial atrophy or asymmetry. Slight prominence of the left sternomastoid muscle — small hollow above the clavicle on the right. Motions all normal. Head straight. Wore brace two months. See photo No. 4.

9. H. A. Boy, age, four and one half. Torticollis, right. Duration since birth. Forcible delivery. Parents noticed a lump over the right sternomastoid at birth.

Condition. — Contraction of the right sternomastoid.

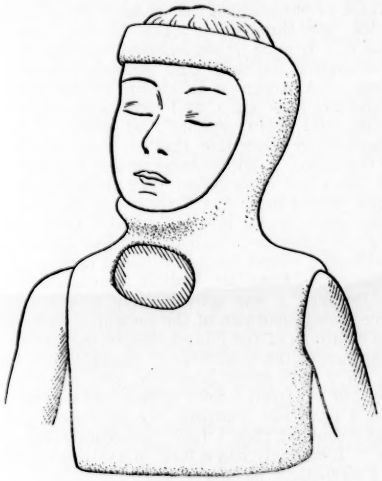
Operation. — November, 1899. Open incision. Myotomy both heads of muscle. Plaster four weeks, followed by Buckminster brace which was worn four months.

Present condition. — Head straight, moved freely in all directions. No atrophy of facial asymmetry. See photos Nos. 5 and 6. No. 5 before operation. No. 6, after operation.

10. C. Girl, age eleven and one-half years. Torticollis right. Duration since birth. Marked contraction of sternomastoid muscle — especially the clavicular portion. Only slight facial asymmetry.

Operation. — February, 1900. Open incision. Myotomy. Plaster for one month, and then Buckminster-Brown brace which was worn for seven months.

Incision in fascia.



Result. — February, 1907, head nearly straight, still shows a slight tipping to the right. Sternomastoid muscle stands out as a distinct ridge as may be seen in photos Nos. 7 and 8, motions of head free.

11. B. C. Girl, ten years. Torticollis, left. Duration three years following the measles. Considerable contraction of the left sternomastoid muscle, no facial asymmetry.

Operation. — September, 1900. Open incision, myotomy. Plaster for five weeks. Brace, five months.

Result. — February, 1907, head straight in all planes. No asymmetry. Motions all normal. See photo No. 9.

12. E. C. Girl, age eight. Torticollis, left. Duration two years, cause not determined. Presents marked contraction of the left sternocleidomastoid muscle with facial asymmetry and atrophy. There is also a well marked degree of forward resistant shoulders and lateral curvature with reversed rotation.

Post-operative plaster cuirasse.

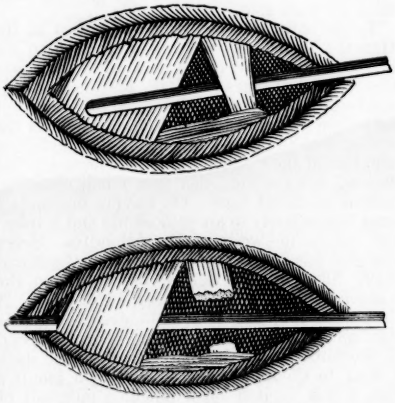
Operation. — August, 1902. Open incision and myotomy. She was put up in a plaster in the usual way and then fitted to a brace. The condition she presents to-day is not wholly satisfactory, for her brace was not worn consistently, which, combined with her lateral curvature and the forward shoulders prevented her complete cure. She is now under treatment for her lateral curvature. See photo No. 10. Photo No. 11 to show over-correction with the Buckminster-Brown brace as applied after an operation for a left-sided torticollis.

All of the acquired forms of torticollis responded as readily to treatment as those of the congenital type. Those cases which were not benefited or had recurrences were in the main due to the unwillingness of the parents to keep the brace on the proper length of time, and to have the child kept under frequent observation at the hospital.

The average length of time during which the child wore the plaster cuirass was about four to six weeks, after which the brace was applied to be worn for about six months, depending upon the individual conditions.

CONCLUSIONS.

In view of the results of the study of this large number of cases, covering such a long period of time, the writers think that the following conclusions may be stated, namely:



(*a*) That congenital or acquired muscular torticollis may be cured.

(*b*) That an open incision, with complete division of the two heads of origin of the sternocleidomastoid muscle, is all that is necessary, except in unusual cases.

(*c*) That the horizontal incision below the clavicle in the line of the skin cleavage is the best to use, in that it gives adequate room and also gives the best cosmetic results.

(*d*) That plaster of Paris is the easiest applied, holds the head in the corrected position, and allows ambulatory treatment, and is therefore the best immediate dressing.

(*e*) That the plaster cuirass should be worn not longer than two months.

Showing division of clavicular and sternal origins.

(*f*) That the Buckminster-Brown brace, Thomas collar, or wire collar should be worn for an average of four months following the removal of the cuirass.

(*g*) That it is best to operate on cases between the ages of two and twelve years, to insure a good result, and prevent permanent bony deformity of the face and head.

Plans for a new building for the medical school of McGill University have been accepted by the Board of Governors, according to the *Medical Record*, and it is expected that the work of construction will commence without delay. The new building will be erected opposite the Royal Victoria Hospital, and is to consist of a central block facing the campus and connected at either side with pavilions running parallel with University Street and Carleton Road.

A SEARCH FOR A SUITABLE CLIMATE.*

BY SAMUEL A. FISK, A.M., M.D.
(*Formerly of Denver, Colo.*)

PART I.

BORN in Massachusetts, I spent six of the first seven years of my life in St. Paul, Minn., where I had "lung-fever," in consequence of a servant, whom I was teasing, throwing a pail of water over me. This simple thing has influenced my whole life, for, from that time, my lungs have been my weak spot.

In the spring of 1880, while a student at the Harvard Medical School, I was confined to my bed constantly for four weeks with what was then called "acute lobular pneumonia." It was before the days that we hunted for bacilli, but they were probably there. The character of the attack, and the care and skill of the physicians who passed their opinion upon the nature of the disease, warrant the belief that I had consumption of the florid type. On leaving my room I went immediately to an outdoor life and a splendid table, in western Massachusetts. Seven weeks of this and two weeks of examinations and worry filled in the time to my going to the Rangely Lakes, which I found awfully hot. I then went into the White Mountains, where I staid until the first of September. On the second of November I was in Denver. After ten days I went to Colorado Springs, and in a month's time I was located on a ranch, a mile out of town. The first of April, of the year 1881, saw me in a small frontier town, Poncha Springs, one of the toughest places in this country, trying to practise medicine. I took a thoroughly unexpected trip back to Massachusetts that fall, and was gone six or seven weeks. The summer of 1882 found me the resident physician at Estes Park, Colorado. That fall and winter I spent in western Massachusetts, where I had strong hopes of remaining. However, an opening, with a fellow-classmate, took me to St. Paul, Minn. Desirous as I was of staying there, the melting snow, the penetrating chill of the air, the fur overcoats of the old-timers, worn on the first of April, and finally a chill, made it apparent that this was no place for me, and so I went back to Colorado. I shall not soon forget the grateful warmth and dryness of the air on the plains west of Omaha. This has been an oft-repeated experience. I wish now to record a trip to Salt Lake City, over the freshly completed branch of the D. & R. G. R. R. On the first of May, 1883, I opened offices in Denver, Colo., and my experience there covers a period of fifteen years, during which time I was in very active work, and handled, as my fellows of this Association know, hundreds upon hundreds of cases of consumption. Six months after opening offices in Denver, I was attacked with inflammatory rheumatism, and coincidentally with a diabetes insipidus, or at least a polyuria, which has lasted ever since. The record shows that on leaving college I weighed 151 lbs. I ran down under this attack to 124 lbs. and to-day I tip the scales at 182 lbs. The cough and muco-purulent expectoration were present, and the fever and sweats were slight, so far as I recall. Since going to Colorado there have been at least two other attacks of pneumonia, a spontaneous fracture of a rib, another attack of rheumatism, the passage of tenia, the colds, sore-throats, etc., that mortal flesh is heir to. It must be remembered, too, that I was a stranger in a strange land, working hard all the time. "A workman is known by his chips." Time and time again, as I have been about my work, and more especially at night, I have thanked my lucky fate that my lines were cast in Colorado. I did not spare myself, but went at all times and everywhere. For years I walked, while others rode; and I always endeavored to keep warm, and I invariably had a good appetite. My digestion was good, and was considered, although I aimed not to be, finical or over-nice. Finally the American Medical Association came to Denver. I was active in the work of that time, being chairman of the section of medicine, the chairman of the finance committee, the vice-chairman of the committee of arrangements, etc. In all I held seven positions, and when that meeting was over, I went to bed, had a masseur, and I have not practised my profession since. Many thought that I had "progressive paralysis." I certainly had a form of ataxia probably of a circulatory nature.

Since then, for six years and a half, I have been a wanderer, living in steamer trunks. I spent several months, in the spring of 1901, in California, and was there with this body again in 1902. One winter I was in Nassau, Bahama Islands. I have been in the British Isles four times in all. One summer I was in Nantucket for several months consecutively. Once I was as far east as Sidney, Prince Edward Island, the Provinces, etc. I have been repeatedly at certain points of the Maine coast. I have wintered and summered in the hills of New England, and now have my home there. I have been to my old home, in Colorado, time and again. The cities and the country have seen me; and all the time I have endeavored to lead the "simple life." I have walked hundreds upon hundreds of miles, slept hours upon hours; and have eaten well, but simply.

My reason for wearying you with this long personal narration is that it must furnish the basis for what I have to say. The figures can and must be looked for elsewhere.

When the trouble with my lungs attacked me, I was supplied with money, not lavishly, but in amounts sufficient to take me, and care for me within reason. I thus came under the class that has been wisely spoken of elsewhere, that could do as seemed best, — the class whose pocket-books are not masters of the situation. From the time that I began to work, in 1881, I have practically paid my way.

The problem that presented, in 1880, was that of a man, unmarried, twenty-four years old, having a college and medical-school education, and a

* Read before the American Climatological Association, at Washington, D. C., May 7, 1907.

moderate purse, quite moderate; broken down with consumption. There were not, nor have there ever been, hemorrhages, and there was a good digestion, and a disposition on the part of the system to repair. I was sent to Colorado, and to Colorado I went, as thoughtlessly as any young man; my medical training did not cut any figure with me. I was sent and I went. In those days Colorado was not the Mecca for the consumptive that it has since become. I regard the choice as in every way a wise one. Why?

Colorado is pre-eminently a land of outdoor life. The constant sunshine invites and it is hard not to yield. This factor of constant sunshine is one on which too great stress cannot be laid. We all know what it means to get out of bed into a flood of brilliant cheer, and it is a great thing to have that cheer stay with one all day long, and day after day, week in and week out. The lack of it is very noticeable to one coming away from Colorado. It is a good deal like getting up at a hotel into a room on the court, one never knows what sort of a day it is. It affects one's spirits all day long. The air of Colorado is remarkably pure and dry. A collection of human beings always affects the quality of the air, and Colorado is wide. The dryness holds most anywhere in the state. It is a rare air, of an elevated region, and the barometric pressure is small. There is a moderate, very moderate, annual precipitation, and the drainage and the character of the soil favor soil dryness. There are about two hours of sunshine at Denver, on the first day of January, to one at Davos. Figures on all of these points have been presented to the profession again and again; they are accessible to any one, but the facts cannot be emphasized too often, in my opinion. Are these simple figures to be juggled with, as one turns a kaleidoscope? or do they hold a vital truth? There are those who say that in the cure of phthisis pulmonalis climate does not cut any figure, that change of climate is the thing; or rather that change of climate combined with suitable diet and regimen. These latter factors can be had almost anywhere, and undoubtedly do play a strong part in obtaining an arrest or cure of the disease, but one cannot get them on the Atlantic coast, or on the Pacific coast, either; or on the Lakes, or in most places. The Colorado air does not come bottled up like a table water, and if one wants it he will have to go after it. Beef-juice, eggs and milk, diet, drugs, brick buildings, etc., are to be had almost everywhere, but the peculiar combination of climatic factors, of which we have just spoken, has to be sought out, and I, for one, think that they are well worth the search.

It is possible to get some of them, separate from the others, at some other places. For instance, one can have sunshine, a dry soil and a pure air (when the wind is north, or northeast, right off of the water), for some of the winter months, at Nassau. But with it comes the additional facts that Nassau is far south, only a little over 25° north of the equator; that it is tropical in its climate; that it is depressing in its effects, and when the wind blows from the points to the south, and over the island, as it frequently does, it blows in a perfect horde of mosquitoes; that the water is cistern water, for Nassau is on a coral reef and the well-water is full of lime; and that the air may be pure, but it is frightfully humid. One would only go there, at the best, for a few months in the winter, to get away from the rigors of the winter further north, and instead of furs one would be wearing muslins, and be thoroughly uncomfortable at that. Nassau is depressing and does not tend to build one up. It is not the place, at all, for one looking for an arrest of this disease. Why bother about it? Some cases of fatty heart, some cases of Bright's disease, some with enfeebled circulation, from any cause; persons somewhat advanced in life, looking for equability of temperature and a moist skin, find Nassau, with its malachite sea and tropical foliage, very attractive. But for a young person looking for an arrest of consumption it is not to be considered for a moment.

A semi-tropical climate is that of southern California. It is neither as depressing as Nassau, nor nearly as invigorating as Colorado. The extreme south is about as far south as Charleston on the Atlantic coast. The climate partakes more nearly of that of the tropics. The palms, the eucalyptus, the pepper trees, are the chief foliage. In southern California proper, one does not run across the verdure to which we of the Temperate Zone are accustomed. An occasional beech is to be found in some of the cañons around Ventura. I well remember how grateful it was to me to find a large cluster of elms in front of the hotel at San José. Sitting in front of a blazing fire in the hills of Massachusetts, or trudging through the deep snows of a New York town, a winter spent amongst the roses or orange trees of southern California seems Elysium. It certainly is unaccustomed. But it must be remembered, for our purpose, that these luxuries are accompanied by *fogs*, dense and wet fogs, and that moisture of the air is very bad for the consumptive.

No one attempts to sit out of doors after sundown in southern California, and they do that in Nassau. It is not an unusual thing to find the asphalt around the hotel at Coronado quite black in the morning, from the moisture precipitated over night. In the morning the fog comes rolling in from the ocean, and it is frequently eleven o'clock before this bank of fog is cleared away so that the sun really shines. I recall that on our visit there, in 1902, one of our ex-presidents went around with an umbrella in his hand, prepared for rain. The old-timers did not carry theirs, they knew better.

We are told, in an article in our Transactions for 1904, that the writer witnessed a foggy spell of seventeen days' duration at Santa Barbara, in May and June of 1903, but he adds, "The fogs, being high, do not cause the deposit of so much moisture as one would expect from an eastern fog, or 'sea-turn.'" The writer on climate, in that charming little book, "Two Health Seekers in Southern California," says (page 142):

" Other consumptive patients find southern California entirely unsuited to their particular malady." As he has already practically eliminated hemorrhagic cases, the so-called catarrhal forms of pulmonary disease, the catarrhal phthisis of the older writers, the phthisis florida and the laryngeal phthisis, it does not leave much else for his group called " other consumptive patients." These two writers are residents of southern California. They are careful observers, and are telling what they see. Figures, too, show that there are over twice as many grains of moisture to the cubic foot of air in southern California as there are in Colorado. It is really a moist climate, and as such it is not suited to the consumptive in search of a cure.* It can be used and used wisely, too, for so many other conditions than consumption, that it should be given its just place by this Association. The roses are perfectly delightful; the climate is soft and soothing; the oranges we all know, but not in an orange-grove; it will stick in one's memory to sit by the gentle Pacific and hear the waves come in. Southern California is so charming, in so many ways, that there is no need of her claiming to be a panacea for everything.

It is claimed that the air of mid-ocean is remarkably pure, and one can sail the ocean blue in search of health. Having crossed the ocean between here and the British Isles eight times I can speak on that score, too. I am particularly fond of the water, and have had the good fortune to escape sea-sickness so far. I have experienced some pretty rough weather, too, and I have always enjoyed it. But however pure the air may be, I have found the vessel to seem cramped, and after a few days have longed to stretch my legs on shore. I have missed the babbling brook, the green meadows and the trees. I have wearied of looking over the rail at the gull or the porpoise. The milk and eggs do not seem altogether fresh. In one way or another I get tired of a vessel, and am glad to get ashore. It seems to me that this feeling would be intensified if one felt that he had to stay there, and moreover the ship diet would be a serious obstacle.

The hills of New England are unnecessarily severe for the invalid, and do not offer the inducements that one can get elsewhere. I cannot understand how the hills of New York can be much better.

It is argued against Colorado that it is not an all-year-round resort, that it is too severe there in winter; and to meet this objection, very largely, it has become the thing, of late, to send one's patients into New Mexico or Arizona for the winter months. This custom, it seems to me, is to be deprecated very much. I have rarely seen much good come of it. These are not the places in which the doctor, at home, wishes to put the patient; if for no other reason than that it is too hot by summer. In making the change back and forth, something amiss is likely to happen to the invalid, and one such fatal mistake costs so much.

Colorado is an all-year-round resort. That is just what it is. The arrest and cure of consumption is not a plant of hasty growth; in many cases it takes years. That state offers abundant opportunity for all the energies that any man can put forth. The danger is that the temptation may be too great. The temperature is not equable, I will admit it. I have thought this a point in Colorado's favor rather than against her. This freshness of the air is invigorating, it is stimulating, and the person seeking a cure is not seeking an opiate as well.

This brings up the point I wish to speak of, and in such a manner as to emphasize what I have to say. The arrest and cure of consumption requires courage, boldness. Is it an easy matter for the invalid to sleep out of doors, in the East, during our coldest winter weather? If the patient is not willing to make an effort to help himself, the attending physician has an almost hopeless task ahead. It is like a drowning man saying, " I will drown and nobody shall help me."

Another objection that is raised is not supported by figures. Colorado is frequently spoken of as being " windy." A careful investigation of statistics, furnished by the Weather Bureau, shows that the average daily velocity of the wind, in Denver, for a period of ten years, was much less than that of Philadelphia or New York, and that it was 85 miles less than that of Chicago and 101 less than that of Boston for the same time.

The question of atmospheric electricity I do not understand. I do know, however, that the air of Colorado is charged with this electricity, and that in the winter time it is very much in evidence. The clothing will snap, at night, as though one had rubbed across the carpet, in order to produce it.

Solly says that the tendency to hemorrhage is lessened in a high climate. Be that as it may, Reed, of Colorado Springs, pointed out to the State Medical Society, that hemorrhagic cases did well in the high altitude of Colorado. My own experience, and that of others, would tend to confirm this statement, very decidedly; *i. e.*, altitude *per se* is not a producer of hemorrhage of the lungs.

Quite a number of cases of laryngeal phthisis have been known to have been arrested. I had them in my own practice, and others did in theirs. Of course the ulcer left a cicatrice on the cord and the voice was affected. But the ulcer was healed, and loud and sustained speech was the rule. I have known this recovery, if it can be called a recovery, to last for years.

In regard to a return East to live, after a recovery obtained in Colorado, many persons fear, or say they fear, that, if they go to Colorado at all, they will always have to stay there. " Once in Colorado always in Colorado," they say. Even if that were so, which it is not, many a worse thing might happen. As has frequently been pointed out, Colorado will fully occupy any energy

* Hermann Weber says, " Another idea, that equable climates are the best in the treatment of phthisis, should likewise (in addition to a warm climate) be much restricted."

that one may see fit to give her, and she is capable of giving large return on all such ventures. Our Dr. Knight, for whom we hold the deepest affection, and whose judgment is so universally admired, put himself on record, on this point, way back in 1891, when he said before this Association, "I feel sure that patients cured in Colorado need not all remain there." My own belief is shown by my action. This principle is well established now, by many and indisputable cases. They occur in practice after practice. It is a good plan, however, not to swap horses while crossing a stream, and to make reasonably sure before trying any experiments.

This brings me face to face with a consideration of the so-called "home treatment." There is not one of us, I think, but would put himself in the best condition possible to overcome this disease, if he felt certain that he had it. He would take the best steps he could, all things being considered, and that right away. He would not fondle the disease. He would not play with the fire, but would take the most active steps to put it out. The best would be none too good for him. Why should he not do the same by his patients? Early diagnosis, and fresh air, combined with food, can do wonders, even at home. It seems wise to me to take every step, and that early and not as a last resort. The alternative is death, of a horrible kind. Why play with it? The question of what to do after recovery can wait. First secure the recovery. Don't ponder about getting there before the doors are closed, but go. Colorado may rule you out, instead of your ruling her out, and her help is needed.

This means, of course, that Colorado climate must be used properly. It is not enough to simply get there, and then, metaphorically, draw a razor over one's throat by doing all sorts of imprudent things which would not be entertained for a moment at home. But the climate, rationally used, is a great aid to the arrest and cure of most forms of phthisis. Experience has shown this to be true, in thousands upon thousands of cases. It is not every case that even then secures a recovery. Many die. Just so with antitoxin, the mortality is greatly diminished under its proper use, but patients still die of diphtheria. If you have phthisis pulmonalis you will, if you are wise, take every step you can to stamp it out, to make your own calling and election sure.

A STUDY OF SEVEN HUNDRED AND FIFTY FRACTURES OF LONG BONES OF THE LOWER EXTREMITY, WITH SPECIAL REFERENCE TO THE CAUSE OF DELAYED UNION.

BY LUTHER G. PAUL, M.D., BOSTON,
Surgeon to Out-Patients, Carney Hospital; Instructor in Surgery and Assistant in Anatomy, Tufts Medical School.

THROUGH the courtesy of the Trustees and Surgical Staff of the Boston City Hospital I was permitted to examine the hospital records in the preparation of this paper.

This series of cases was taken from the surgical records of the Boston City Hospital from 1890 to 1900. Fractures of the femur, of the tibia alone, and of the tibia and fibula together were taken. Fractures through the neck or condyles of the femur and through the heads or malleoli of the tibia and fibula were not included. Simple fractures of the shafts of the bones were the only ones studied. No compound fractures were considered.

For the purposes of this paper all fractures which did not unite within the normal limits were regarded as cases of delayed union, no distinction being made between delayed union and non-union.

This series comprises 281 fractures of the femur, 136 fractures of the tibia and 333 fractures of both tibia and fibula.

FRACTURES OF THE FEMUR.

There were 281 of these fractures in 276 patients, 217 of whom were males and 59 females. Five patients had both femora broken. The right femur was broken in 150 cases and the left in 131.

The fractures occurred at all ages. The youngest patient was eight months old and the oldest eighty-three years. The frequency of these fractures in youth is shown by the fact that 38% were in patients under ten years of age and 50% were under twenty years. Twelve per cent of the patients were over fifty years of age.

The majority of the fractures were through the middle portion of the bone, that is, 32% were at the middle, 33% at the junction of the middle and lower thirds and 23% at the junction of the middle and upper thirds, leaving only 7% through the upper third and 5% through the lower third. There were no fractures through the upper third of the femur in patients under ten years of age, and only 2 in those under twenty years. In the first five decades the majority of the fractures were at the middle of the femur or below, while after fifty years of age there were nearly twice as many fractures above the middle as below it, showing a tendency for the high fractures to occur in older people.

Eighty-three per cent of all the cases were solidly united within nine weeks, 4% left the hospital in less than 9 weeks and before the fractures were solid; 1% died shortly after entrance, 1% were operated upon for delay in union, and 11% required ten weeks or more for solid union to take place.

Forty-four per cent of the fractures which were solidly united within nine weeks were in patients under ten years of age, while of the cases requiring more than ten weeks for solid union only 6% were under ten years; but there were 7 patients over seventy years of age, and in each one of these the fracture was solidly united within nine weeks. Ninety-seven per cent of the fractures in patients under ten years of age were solidly united within seven weeks. Apparently fractures of the femur in children unite readily, but old age does not prevent union within the normal limits.

The following cases were found in the patients who were suffering from constitutional disease:

1. Rachitis, 5 cases, solid union took place in three, four, six, seven and fourteen weeks respectively. The patient whose fracture required fourteen weeks to unite was very poorly nourished.

2. Mitral disease with good compensation, 2 cases, one of which united solidly in six weeks and the other, which is described later, was operated upon for delayed union.

3. Marked arterio-sclerosis, 1 case, solid union took place in six weeks.

4. Malaria, 1 case, solidly united in six weeks.

5. Epilepsy, 1 case union solid in seven weeks.

6. Advanced sarcoma of breast and groin, 1 case, union solid in eight weeks.

7. Tuberculosis, 2 cases.

(*a*) Pulmonary tuberculosis, sixty-nine years of age, union solid in ten weeks.

(*b*) Sub-acute hip disease, solid union in nine weeks.

8. Fragilitas ossium, 1 case, union solid in nine weeks.

9. Diabetes, 1 case, solid union in nine weeks.

In looking for local causes as interposition of soft parts, comminution, poor apposition, and overriding of fragments and obliquity of fractures which might delay union, it was found that of the fractures which united solidly in nine weeks or less 14% were oblique fractures with overriding of the fragments; but of the fractures which required ten weeks or more to unite solidly 40% were oblique with overriding, and in some cases comminution of the fragments. The end results showed that in 4% of the former class there was some slight resulting deformity, and in 23% of the latter class it had been impossible to accurately approximate the fragments. This showed a tendency for the cases in which approximation of fragments was difficult to require more time for solid union to take place.

The following cases, three in number, would seem to strengthen this opinion:

1. Male, sixty-seven, an oblique fracture in the upper third of the femur. The limb was put up on an inclined plane with extension, and later in a Buck's extension. At the end of twenty-four weeks there was a shortening of 3 inches and union was only moderately firm.

2. Male, thirty, an oblique fracture of the femur in the lower third. The limb was put on a double inclined plane and later in a Buck's extension. At the end of eighteen weeks there were 1½ inches shortening, and some mobility at the seat of fracture.

3. Male, sixty-three, an oblique fracture in the upper third of the femur. The limb was put on an inclined plane, with extension. At the end of nine weeks there was overriding of the fragments, and mobility at the seat of fracture. At the end of sixteen weeks there was considerable mobility and moderate deformity. In these 3 cases repeated attempts were made to overcome the shortening and approximate the fragments, but without success.

Three patients were operated upon because of delay in union.

1. Male, five years of age, in excellent physical condition, fractured his left femur in the middle third. Abnormal mobility and shortening were present, but no crepitus could be obtained on manipulation of the fragments. The limb was kept in a Buck's extension for two months, when a plaster of Paris spica was applied for one month, but no union took place. The fracture was then cut down upon, and the end of the upper fragment was found encapsulated in muscular tissue, and separated from the lower fragment by considerable fibrous and muscular tissue.

2. Female, fifty-four, very stout, fractured her femur at the junction of the middle and lower thirds. There was much deformity and mobility in all directions, but no crepitus could be obtained. The limb was put in a Buck's extension, later in a plaster spica, and later still in a Buck's extension. At the end of twenty-two weeks there was free mobility at the seat of fracture. Operation showed the fragments overlapping 2 inches, with soft parts between.

3. Male, sixty-two, in good physical condition, fractured left femur at the junction of the middle and lower thirds. There was free mobility in all directions, the lower end of the upper fragment nearly penetrating the skin. The limb was put in a Buck's extension, but at the end of two months there was no union. Operation at that time showed that the upper fragment had transfixed a portion of muscle. The ends of the fragments were freshened and approximated without wiring. Union did not take place, and nine months later a second operation showed the fragments overlapping two inches, and without callus. The ends were freshened again and wired. The bone was solidly united in three and one-half months. This patient received a fracture of the radius at the same time that his femur was broken, but it united without delay.

The interposition of soft parts and imperfect approximation was responsible for the delay in these fractures.

Alcoholism had no apparent effect on union of fractures of the femur.

FRACTURES OF THE TIBIA.

There were 136 fractures of the tibia, 112 males and 24 females; 66 of the right tibia and 70 of the left. Forty-three per cent of the patients were under twenty years of age, 48% were between twenty and fifty years, and 9% were over fifty years; 94% of the fractures were at the middle of the tibia or below; that is, 24% were at the middle, 42% at the junction of the middle and lower thirds, and 28% through the lower third.

All the fractures above the middle of the bone were in patients over twenty years of age.

One hundred and twenty-three patients were under observation until solid union took place, 9 were discharged within five weeks without having become solidly united, 2 fractures were under observation for sixteen weeks without uniting solidly, and 2 patients died a few days after entering the hospital, one of shock and the other of delirium tremens. In no case was an operation for delayed union made.

Eighty-two per cent of these fractures were solidly united within seven weeks, and 9% required from eight to thirteen weeks for solid union to take place. The remaining 9% included patients who were lost sight of, 2 who died and 2 whose fractures were not solid at the end of nine and sixteen weeks respectively.

Twenty-eight per cent of the fractures which united solidly within seven weeks were in patients under ten years of age. In fact, all those in patients under ten years old were solid in five weeks or less. Of the fractures requiring from eight to thirteen weeks for solid union to take place, all but one were over twenty years of age. There were five patients over sixty years of age, and in four of these the bones were solidly united within seven weeks. One fracture in a patient of eighty-two years was solid in five weeks.

CONSTITUTIONAL DISEASES.

Two patients with fractured tibiæ were suffering from chronic nephritis. One of these fractures united solidly in six weeks and the other, showing no union at the end of four weeks, was given potassium iodide for suspected syphilis. His fracture united solidly in twelve weeks.

Alcoholism had no apparent influence on the union of these fractures.

LOCAL CAUSES.

Of 111 fractures which were solidly united within six weeks, in 12% special reference was made to their obliquity and deformity. In 107 of these cases, 96%, good alignment and approximation of the fragments was obtained, and in the remaining 4 cases the resulting deformity was only slight.

Of the 12 fractures which required from eight to thirteen weeks to become solidly united, 4 were oblique with considerable deformity, and two of these were comminuted. No one of these 4 cases was without deformity when union was solid. The other cases showed no apparent reason for delay.

FRACTURES OF THE TIBIA AND FIBULA.

There were 333 fractures of the tibia and fibula together, 82% of which were in males and 18% in females.

Fifty-five per cent of these fractures were of the right leg and 45% were of the left.

The fractures occurred at all ages, but were comparatively rare in children, 7% occurring in the first and second decades respectively. Seventy-one per cent of the fractures were in patients between twenty and fifty years of age and 15% of the patients were over sixty years of age.

Fractures of this class showed a marked tendency to take place in the lower half of the bones, 84 per cent being located at or below the middle. In 10% of the cases the bones were broken at different planes. There were 5 cases in which the tibia was broken in two places, 5 cases in which the fibula was broken in 2 places, and in 1 case there were 2 distinct fractures of each bone.

Two hundred and ninety-two fractures were under observation until solid union took place, the time required varying from three to thirty-eight weeks. Twenty-three patients were discharged within four weeks of the time of fracture and lost sight of. Twelve fractures were observed for more than nine weeks, without uniting solidly, 2 were operated upon for delayed union, and 4 patients died, all of delirium tremens, within eleven days of the time of fracture.

Seventy-eight per cent of the cases which were observed until solid union took place united solidly within nine weeks, while 12% required over eleven weeks to become solidly united.

There were 23 patients under ten years of age, all of whose fractures were solid within eight weeks. There were 237 fractures in patients from twenty to fifty years of age, and sixty-six per cent of these were solidly united within nine weeks. There were 7 patients over seventy years of age. Five of these fractures were solid within nine weeks, 1 patient died eleven days after his accident and in one the union was delayed.

In looking for constitutional diseases accompanying these fractures, the following were noted:

1. Tubercular disease of vertebra, 1 case. A boy ten years of age, fracture solid in four weeks.

2. Syphilis, 2 cases: (*a*) A man, twenty-nine years of age, fracture solid in seven weeks. (*b*) A man thirty-eight years of age, fracture solid in nine weeks.

3. Multiple spinal sclerosis, following syphilis, 1 case. A man, twenty-four years of age, fracture solid in 8 weeks.

4. Tabes dorsalis, 4 cases: (*a*) A man, fifty-two years of age, tabes of seven years' standing, fracture firm, but not absolutely solid at the end of five weeks, at which time trace of him was lost. (*b*) A man, fifty-five years of age, with an uncomplicated fracture, had solid union in nine weeks. (*c*) A man, sixty-five years of age, with a definite syphilitic history, had an oblique fracture, with overriding of the fragments. The end of one of the fragments sloughed through a leg ulcer at the end of seven weeks, and union was solid in sixteen weeks, but position of fragments was not good. (*d*) A woman, forty-six years of age, with tabes for ten years, had an oblique fracture with overriding of the fragments, union was solid in twenty weeks. The position of the fragments in this case was good.

In considering the local conditions which might delay union, it was found that 20% of the cases which united solidly within eight weeks were mentioned as being oblique fractures with overriding of the fragments, and the end results showed that in 92% good approximation of the fragments had been obtained. Sixty-seven per cent of the fractures which united in from nine to eleven weeks were oblique with overriding, and 84% were in good position when solidly united.

Of the cases which required from twelve to thirty-eight weeks for solid union to take place, 83% were oblique, with overriding of the fragments, and in only 62% had it been possible to obtain an accurate approximation of the fragments.

Of the cases which were under observation for more than eight weeks, without becoming solidly united, 89% were oblique fractures with overriding of the fragments. At the time of discharge, in only 39% had good alignment and approximation of the fragments been obtained.

Apparently, as the time required for solid union

to take place increased, the percentage of fractures which were oblique, with overriding, and hence more difficult to hold in good position, increased; while at the same time there was a decrease in the percentage of good anatomical results. That is, fractures in which there was difficulty in getting a good approximation of the fragments, and these would naturally be the oblique fractures with overriding of the fragments, were the ones which, as a rule, required the longest time to become solidly united. There were two cases which are of interest in this connection.

In one case the left femur was fractured obliquely at the junction of the middle and lower thirds and the tibia and fibula of the same leg were broken in the lower third, no mention being made of obliquity in the latter fracture. The tibia and fibula united firmly in nine weeks and the femur required thirteen weeks for solid union to take place.

In the other case both bones of the left leg were broken at the junction of the middle and lower thirds. The fracture was oblique and comminuted. The right tibia was broken at the middle. The right tibia united firmly in five weeks, while twelve weeks were required for the fracture of both bones to become solidly united.

The location of the fractures apparently had no influence on the time required for solid union to take place.

Two patients were operated upon for delay in the union of the fracture.

1. A man, twenty-seven years of age, had an oblique fracture of both bones at the junction of the middle and lower thirds, with much deformity and overriding of the fragments, and considerable destruction of soft parts. At the end of twenty-eight weeks the fracture was still movable. Operation showed that the fragments were overlapping with soft parts interposed. There was some fibrous union.

2. A man, twenty-five years of age, had a fracture of both bones of the leg at about the middle. The fracture was oblique and there was considerable overriding of the fragments. At the end of twenty-one weeks there was still abnormal mobility at the point of fracture. Operation showed overriding of fragments with interposition of soft parts.

The cause of delayed union in each of these cases was evidently the interposition of soft parts between the fragments.

Some of the conclusions which may be drawn from the foregoing series of cases are:

1. In fractures of the long bones of the leg the proportion of males to females is about 4 to 1.

2. Fractures of the right leg are only slightly more frequent than of the left.

3. Fractures of the femur are proportionately more frequent in children than in adults.

4. High fractures in any of these three bones are rare in children under ten years of age, but are found in adults past middle age.

5. Fractures in children unite readily, and old age of itself is not a cause of delayed union.

6. The majority of fractures in which union is delayed are of the oblique or comminuted variety.

7. In the great majority of cases, delay in union is due to local causes, such as interposition of muscular tissue between the fragments, or faulty approximation of fragments.

8. Constitutional diseases rarely cause delay in union, but certain fractures, for some unknown reason, fail to unite, although the approximation is accurate and no constitutional disease is present.

Practically all who have written on this subject are agreed that local conditions, as interposition of soft parts, imperfect approximation of fragments, imperfect immobilization, etc., will delay or prevent union of fractures, but opinions differ as to what extent constitutional diseases will influence union.

Bernays says, "All cases of non-union which are not cured by proper approximation and immobilization are incurable, and are due to some unknown cause, or to some of the well-known constitutional vices, such as the different forms of malnutrition, cachexia and debility."

Bennett: "Fractures in persons who follow trades in which they handle lead, as painters, are apt to have delayed union." Birdsall recognizes both constitutional and local causes, and says, "The provisional callus is much greater where the bone is surrounded and well covered with muscular tissue. At least one third of the surface of the tibia has no muscular covering, therefore the fact that so large a surface of the tibia is subcutaneous is not an unimportant factor in delayed union."

Cheyne mentions the usual local causes, but thinks that alcoholism may distinctly retard union after fracture, that specific fevers during the progress of the case cause delay, and that when the fracture is in a rachitic patient, an abundant callus is thrown out, but normal ossification does not take place. He believes that general debility, old age and paralysis will cause delay in union.

Dunn thinks that in cases in which local and constitutional causes are not present, apparently the bone forming power of the cells is inhibited from some unknown cause.

Fisher, among other causes, mentions deficient blood supply due to relation of the fracture to the nutrient artery. Girdner says, "In cases of general paresis, non-union or soft fibrous union is the rule, and firm, bony union the rare exception." Park says that simple, delayed union may be caused by shock, old age, rachitis, gestation, lactation, scorbutus, syphilis, cancer, paralysis and local unrest; and that non-union may be due to the above causes or to faulty fixation and interposition of soft parts.

Exophthalmic goiter is given as the cause of delayed union in a fractured humerus, by White.

Pilcher leans toward the side of constitutional causes and thinks imperfect immobilization is not a cause of delayed union.

Snévé says syphilis does not cause delayed union unless the bone itself is the seat of the disease, old age and pregnancy are not factors, and that non-union is wholly and entirely a trophic matter dependent upon injuries to the nervous supply of bones.

Adams reports four cases operated upon for non-union. He considers "general lack of nourishment to the parts resulting from age" as the cause of non-union of a fractured femur in a man sixty-five years of age. The other three cases were due to local causes. Carothers thinks fibrous union is most likely to occur where immobilization is difficult, or neglected in treatment, while Callender says, "I have never seen the union of an ordinary fracture prevented by age. Even paralytic old people repair a fracture rapidly." Again he says that pregnancy, debility, paralysis and syphilis are no obstacle to the repair of fractures, and that all the cases of non-union of the bones of the leg which had been under his notice were instances of oblique fracture.

Fowler thinks alcohol does not interfere seriously with union, that the cause is usually local, and in certain cases no rational explanation can be given.

Oppenheim, quoted by Hartshorne, says that general cancerous conditions and syphilis do not retard union.

Senn thinks that old age and injury to the nutrient artery have no influence in determining non-union.

Murray, after a study of 76 fractures of the tibia and fibula, concluded that oblique fractures caused more displacement, lacerated the soft tissues and required longer to unite.

Stimson sums up the question as follows: "Certain general conditions have been deemed a cause of delay or failure of union, either through a specific poison as syphilis, or through deterioration of the health or a lowering of the vitality induced by them, as pregnancy, lactation, defective nourishment and acute diseases; but it is beyond question that the causes are usually local and that the most common one is a faulty relation of the fragments to each other, including therein the interposition between them of muscular tissue. Other causes are defective innervation, diseases of the bone, inflammation on the surface and defective treatment. It is also true that delay and even failure may occur, when no local or general cause can be found, when the fragments are in exact apposition and when the general condition is good."

The following tables may prove of interest:

HABIT CURE, MENTAL AND PHYSICAL.

BY JOHN WARREN ACHORN, M.D., BOSTON.

HERE is a commonsense problem for solution: A child at birth should have healthy automatic instincts, — for yelling, kicking, nursing. These come without rhyme or reason, unconsciously, except for those who have to listen to them. A child apes those about him and soon gathers, during the formative years, a basketfull of habits, aside from involuntary practices. Later on other factors mix with the development and play a part in the evolution. Finally the child is made up of a batch of consciously or unconsciously acquired habits, mental and physical, good and bad, which he controls in part and in part surrenders to according to the understanding he has and the beginning character he possesses, depending mainly upon mother teachings. Equipped, then, according to instincts, temperament, inheritances, parents, playmates, surroundings and education, he graduates finally into the world's arena.

If the first thought-impulses that traverse the wilderness of a child's mind are disturbed by parental anger, nagging criticism or other discipline irrational in character, the chances are that distrust of self will develop in the child. An initial thought or impulse, like a trail through the wilderness, should be laid down as nearly right as possible. Thoughts, like explorers, are prone to follow a "blazed trail" instead of swamping out a new and better one, even if it is known to be poor. It is this spirit of nagging criticism, so prevalent in New England in past time, in the case of children, during the vital formative years, that is responsible for many failures and much unhappiness in mature minds even. Children can be taught the fundamentals, — honesty, love, loyalty, appreciation, reverence, patriotism, work and play, without being made the victims of a guilty conscience, — right or wrong, you're wrong, is one way of defining it. Praise of the right sort acts as a nerve tonic; it is constructive, while adverse criticism stunts growth and fosters morbid mental impulses. A child should never be nagged until the burden of his formative day, through worry, distrust or other cause, is dragged into the night. Every morning he should be taught to start afresh, and when the sun goes down, that day for him should end, — it is past experience. This way of doing might be practised by everybody; the night is a poor time in which to criticize one's self for the imperfections of a day that is done; it is a poor time in which to do business, properly the work of the day.

We are privileged to use past experience as a guide to the future, but it is not to be looked back upon with regret. Looking backward fosters introspection and retrospection, both bad habits of mind; it fosters worry, the guilty conscience habit, and that of turning night into day, with consequent loss of nervous force from loss of sleep. If children, or any of us, for that matter, were made perfect in the beginning, we should have nothing in this world to do *really* worth working for. We should never willingly surrender any experiences of life; they make us what we finally become, a reflection of the best there is in us. Every expression line in our faces is an indication of self-building or self-denial in some direction, or should be. We are respected and loved by those about us as we grow older, because we have made a winning fight. The whole question is one of character building, or becoming one's own master, of finding one's self.

As the result of our training or lack of it most of us have come to be afflicted with physical and mental habits, which breed functional disorders, the persistence of which makes every-day life and living more or less of a nightmare.

For mental faults we have fear, false pride, over-sensitiveness, selfishness, envy, avarice, introspection, retrospection, obstinacy, loss of temper, jealousy, worry, hurry, — often due to procrastination, — hysteria and insomnia, along with many others. For physical faults, we have gross habits of eating, eating hurriedly, tea and coffee drinking to excess, neglect of regular bodily habits essential to health, neglect of sleep at the right time and in the right amount, surrendering to physical passions and desires known to be morally, if not physically, detrimental to health, or one's sense of well being, lack of cleanliness, alcoholism, the tobacco habit and many others. The one set has its habitat "above the ears," the other set "below the necktie," but they are one and the same thing, they are all habits or weaknesses due to our mental or moral make-up, vacillating or strong as the case may be, but they are all manageable or curable, provided the victim is not a degenerate, and has character enough to "nail to," or is willing to "hustle" for character. The cure is applied common sense simply, and the cultivation of one's power of resistance, until the mind and not the habit, whether mental habit or physical habit, is master.

Let us regard the thinking mind as a thin plate covering the floor of the brain just above the eyes. Above this plate worry, fear, anger, insomnia and the like have their habitat; they are

the "rowdies of the mind" in the attic of the brain, who, by their unruly actions, keep up such a disturbance that the better habits, peacefully disposed in the rooms about, cannot work to the best advantage to generate impulses or forces that are constructive, elevating, or spiritual. Below this mind plate are the body habits. We will locate them "below the necktie," for the sake of attaching them to the body itself. Gross eating, hurried eating, tobacco chewing, candy eating, liquor drinking to excess, physical negligence and immorality, belong to this class of body habits.

People who are mentally and physically miserable, but suffering from no organic or infectious disease, often know why they are miserable, but they seldom make an unaided attempt at a cure, — such is the hold habit has upon them; and they do not voluntarily confess the fault or the cause, either to themselves or another, unless invited to do so, as at a confessional. The first essential to the cure of any habit is a willing mind. Will any one admit he hasn't character enough developed, in the course of a lifetime, perhaps, to conquer a habit, if it detracts from his usefulness, his happiness, or the comfort of those with whom he lives? If the habit is mental, a "rowdy in the attic of the brain," the mind of the sufferer is to be turned up; or if the habit is one of indigestion due to beans eaten at bedtime by a man over seventy, the mind of the victim must be turned down. The habits of childhood are all abandoned, as the years go by, such as playing tag, sliding knee-fashion on a sled, one and all except the habit of eating. Candy eating, for instance, properly goes with quick digestion and the activities of childhood; it is often persisted in to old age, greatly to the physical detriment of the individual who declines to relinquish the habit. The food that digests well at twenty is not necessarily the food that fits best at sixty, and yet who interests himself to find this out? Food, like everything else, should be changed or modified with advancing years, to meet the physical needs incident to lessening activities, both physical and mental. We eat, or should eat, only what is required to keep the blood pure and bright, for the blood goes everywhere and nourishes all the tissues. When food is properly eaten, less is required and the stored-up nervous force is not wasted getting rid of it. The system relieved of this burden of excessive food saves an amount of energy equal possibly to that used by the brain in its daily round of work, while the increased amount of mental vigor that follows the use of food up to what is physiologically required, but not beyond it, is sufficient proof of the nervous force otherwise dissipated in this way. Proof of this is within the reach of every one who cares to demonstrate it. The extra strain imposed upon the human machine, from over-indulgence, must wear it out years ahead of its time. The assimilation of too much food renders the blood current impure; these impurities clog the connective tissues everywhere and cause many of those chronic disorders from which people of mature years suffer. The better assimilation of properly masticated food, which is the first essential, in just the amount required, maintains the blood in its purity at its highest nutritional standard. Lust for food satisfies the baser instincts only. It stimulates sensuality, the inferior passions and desires, and robs man of his spirituality. Animal force in a flight of oratory may win the applause of the multitude, but never the hearts of the people. A mind "crowned" with over-eating may capture a city, but not the man at the head of the procession. If spirituality is one of the things needed in this world to offset its "splendid materialism," food properly eaten, thoroughly dissolved by the teeth and tongue before it is swallowed, is one way of gaining some of it. Plain living and high thinking work well under the same yoke. Perhaps the secret of longevity, sought for in fabled springs and patent elixirs, lies hidden in the proper utilization of our every-day foods, in marriage founded upon health as well as sentiment, coupled with moderation in all things.

Turning to the habit above the mind plate, let us discuss worry. Every one knows, or should know, that this is a form of nervousness, a mental condition and not a physical problem. It has no substance in fact and cannot be reached by drugs. The cultivation of a better habit is the only cure, and persistence in the attempt the only safeguard. There is no question but worry greatly impairs the physical well-being; it retards digestion and prevents natural sleep. During sleep is the only time when the nervous system is repaired; food when properly eaten and digested furnishes the material for repair. Yet worry or undue solicitude is classed below fear, which is defined as a painful emotion. Hypochondria is even more pitiful than worry; it is defined as "belief in a serious disease." The person who wills, wins; the person who *tries*, presupposes that he is going to fail. The *will* to do a thing has faith for a companion, while trying to do a thing has failure for a mate. It is good practice never to face a worry. If this worry is represented by some one in anger, turn on the heel and walk away; if it is in the mind, a happy thought, if possible, should be substituted for the ugly one. With practice this can be done. A happy experience, a fascinating story, a sentiment that appeals to the higher intellectual faculties, a short walk, the companionship of some one for a time whose moral courage fosters one's own, these and other resources within the reach of every individual, however humble, if cultivated, will serve as deliverers from this harpy or "rowdy of the mind," or any of the other habits mentioned, for that matter. At first breaking away from habit is difficult, because the mind doesn't respond to the feeble cry of the better impulse for recognition, the older habit being the stronger and much more readily started; but in the face of persistent patience the bad habit gradually weakens and finally the better one registers first on the dial of impulse, with sufficient force to maintain the balance of power, when the old habit, like a prairie coyote, slinks out of sight,

and wonder lingers entranced that such a weakness could ever have existed. These harpies of the mind often return to roost in their old accustomed places or on some other piece of mental bric-a-brac. Gun for them, persist in winging them, and in time they will all be bagged and the mind cleared; this is often a task, but it is a feasible one. However much these birds may fly over our heads we must not let them build nests in our hats. The thought that flits does no harm, the thought that sticks does harm.

All New England says, " he don't," instead of he doesn't. This is an error in grammar, a matter of habit. If any one having this fault of speceh and desiring to be rid of it will say, " he doesn't "; twenty times a day, and get some friend to tell him when the " he dont's " are numerous, if he will repeat a sentence with " he doesn't " in it frequently, and put a printed " he doesn't " on a slip of paper, where he can see it on his desk, or in front of his dinner plate, after a time the " he doesn't " gets into the memory of the mind and the " he don't " gets out. Finally, the " he doesn't " in every sentence in which it should appear will be seen in advance of the " he don't "; as the words come romping along to form a sentence, the " he doesn't " takes its place and the fight is won. Oblivion settles over the old way, and grammar may be seen walking down the avenue of thought and expression on the right arm of memory, not on the left. This correction illustrates how one can make a new road, or better one, through the brain in place of the old trail so long used, since childhood probably.

A man suffering from insomnia will often establish this fact in his anatomy by sitting up regularly half the night; or, perhaps, about sunset he begins to say, " I can't sleep," and then keeps on vaccinating himself with this idea until saturated with it. Of course he knows he can't, he has been telling himself this for ten years, and he lies awake to prove it. Let him begin by saying, " I shall sleep "; let him say it forty times a day, — say it until the memory of " I can't sleep " fades and the affirmation " I shall sleep " takes its place. This comes about gradually, but finally the body of the person who *can* sleep, because he says he will, begins to relax, and impulses of a soothing, constructive character begin to travel the strained and dessicated nerves. Let the person suffering from insomina go to bed early. He is not to try to sleep. Sleep always runs away if chased; it is another prairie coyote if ever there be one. Mark Twain once said " that the coyotes he chased looked like gray streaks going, and they left a hole in the air where they whipped through." The person afflicted should remain indifferent to the question of sleep, after retiring. Those who have faith can help themselves by asking God to help them, — he surely will. It is certainly a comfort to have some higher power to which to appeal. One man, cured, prayed to his wife; she had been dead two years, and he had suffered from insomnia fifteen years. He loved and idealized her more than anything else; he was told she was not far away, that she simply had gone to join the Great Force that sent her here and had taken her away; if he prayed to her, he prayed to God who stood beside her listening. The influence of loved ones who have passed on never grows less with the living. The influence of every good mother is greater as her children, men and women, advanced in years, grow to appreciate the beauty of her life character. The only physical request made of this reluctant sleeper was, that he should take his every-day mind and hold his body still in bed with it, and not turn and twist as he had been accustomed to do; he was told that in time his mind would become positive instead of negative, and when his body relaxed, under the influence of affirmative auto-suggestion and positive memorization, with God's help, he would sleep. In six weeks he slept.

By various means and for various reasons, individuals will overcome any habit they decide to conquer, for all persons are not equally spiritual; but all seem to require some guiding purpose or inspiration. Love of children, faith in the advice of a friend, faith in the advice of a physican or of the minister, pride of the right sort, ambition, love of family,— these are the moving causes in many cases; then there is the desire to avoid sickness related to the persistence in some bad habit, or the desire with some to have nothing in their lives that might not be known, that might not be a universal law for all men to follow; and finally, and, best of all, there is the spiritual desire, by far the most potent, — for spirituality carries real faith with it and faith cures almost anything except organic and infectious diseases of a serious nature, while it goes far towards helping to heal some of these. One should cultivate his powers of resistance by any decent or ideal means until he has established right ways of thinking and acting in the place of wrong, and has such habits of body that both the mind and the body become healthy and remain so.

Concentration is one of the things required for the cure of any habit, as well as patient practice and a willing mind. Mental discipline or the ability to concentrate the faculties is what we should get in school or college; experience or real education is what we gain in the world at large. Concentration of mind is the thing that ails a fellow when he falls in love, and this form of concentration sometimes moves the admiration of the world. " Faint heart never won fair lady "; equally so, a faint determination never mastered an ugly habit. If the family man with a habit that is making the family miserable would put half as much concentration into curing his habit as he puts into some business problem, in order to make money that he really does not need and is too selfish to give away, he would soon conquer the habit and be, by so much, the better person. Social etiquette has reached such a fine point, under our modern way of doing things, that the members of the same family, living together, are bound to put up with each other's unwholesome habits, an etiquette which is a hindrance to happiness, when, if they had been

trained in a larger-minded way, they might help each other, and foster better feelings by promoting happiness in the home they share.

Old persons with obnoxious habits are prone to say they are too old to learn; what they should say is, they are too selfish to learn, or prefer to have those about them put up with their "little meannesses," rather than themselves make the effort necessary to wipe out their habits. Such persons are not masters of themselves and never have been. No greater small sin is committed than this petty sin, when one member of the family persists in some habit that works to the detriment of all the rest and persists not for a month but for a lifetime perhaps.

To sum up, then, this question of habit cure; first comes the resolution to do the thing required, then the memorization of an affirmative expression, because it is constructive and toning, a good substitute for the expression that is negative and destructive. This practice should be kept up till memory takes on the affirmative expression, and the negative fades away; and along with this goes concentration of mind or purpose; and finally one should seek any influence known that will assist, such as optimistic friends, reading that elevates, change of scene or thought, exercise or prayer, if one has faith.

Those who suddenly and successfully quit one habit for another are of the hysterical temperament usually and become readily "vaccinated" with a suggestion given them; they become intoxicated with an idea at once; perhaps they are fortunate in that they can be hypnotized promptly and remain so; who knows? For the majority of us the problem of life is quite like all other problems we have ever done; we have to chisel each in turn out of the solid rock of inexperience. It matters little how often one fails, if only his purpose to win is kept in sight; each relapse is less and less serious and the falls are further and further apart.

Competition, the basis of that endeavor by which the world forges ahead materially, develops many habits that balance those which spiritual teachings develop in us. *Competition* is the greatest mental *force* in existence. Against competition the feeble efforts of the world at character building may be compared to a child trying to wrestle with a giant.

With six days in the week devoted to competition and a little more than an hour in the one day that is left devoted to spirituality, delivered at arm's length usually, is it any wonder that many fail and fall as a result of the unequal mental training?

The acceptance of spiritual teachings depends, in part at least, upon the stage of evolution and the practices of each individual. Many men have not been through the coffee grinder often enough. This in itself is a factor from the point of view of evolution. The spark is there, it is in every one; it is everywhere; but the expression of it has not been cultivated, perhaps. Spirituality depends upon cultivation or practice quite as much as upon anything else. Practice makes a good machinist, a good musician, perhaps a good Christian; patience and practice will cure any habit whatsoever, but habit-cure and Christianity represent different stages in human life from that held by the truly spiritual-minded. Christianity is a good habit; spirituality is something more. Christianity obtains when a man goes to church as a matter of liking or duty, or perhaps directs a Sunday school. He may be socially inclined, with organizing ability, enjoys recognition and takes a good job, for which there is pay in praise; or it may be he desires to help others gain an ascendency that he himself cannot understand; this is certainly unselfish and so far as it goes is first class. Such an attitude carries a man above his habits usually, — at least, it should. Spiritual teachings will not always take root in soil where only tares in the shape of worry, anger, avarice or bad habits, whether physical or mental, have been growing. Peace of mind affords happiness for some, perhaps, but not happiness for others. The man who is clean up to his chin, who obeys the written laws, or more especially the unwritten social laws, if he has good health, something to do which he loves to do, and a hobby for the sake of recreation, usually has a good time in living, for he gets along comfortably; but these qualities do not constitute spirituality. The spiritual man is not satisfied with peace of mind, he must be in touch with God through faith. The mind rules the body; the spirit also must have help. One who has a spiritual nature can soon raise his powers of resistance to a high level and weld the link of faith in the chain of his life, so that it becomes as easy and comforting for him o talk with God as it is easy and helpful to talk with a dear friend, and more so.

A man must be taken in hand at that point in his education or evolution at which what is said to him will take root. People at the level of mere good citizenship do not all grasp higher teachings; individuals who indulge in mental practices that distract, or physical practices that debilitate, are poor absorbers of spiritual teachings. A man raised above his physical and mental habits is in a position to cultivate whatever tangible spirituality there is in him. One may gain faith because he has a spiritual side to his make-up, and yet be grievously at fault in his habits; this is probably the established order to-day with the majority of men. Too many people pray in one place and put their bad habits on exhibition in another. Those who have mastered their faults, by just this difference in level, are on a plane above that held by many who profess higher things, and their lives are perhaps more potent examples for good.

These worrying, nervous, threadbare people all about us, broken by the stress of modern civilization, are in need of just such relief as treatment and cure of their habits will afford. Their habits once mastered here, they themselves are better fitted for something higher, — for something far beyond and above Nature even, something so transcendent as to be quite beyond words; for something which profoundly influences life and

the spirit of man, for something compared with which all other things are weak and unprofitable. "For I have felt a Presence that disturbs me with the joy of elevated thoughts; a sense sublime of something far more deeply interfused, whose dwelling is the light of setting suns." May we so live that we may grow nearer this glorious Presence which so exalts the beauties of the world for us.

Reports of Societies.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

TWENTY-FIRST ANNUAL MEETING.
HELD AT WASHINGTON, D. C., MAY 7 TO 9, 1907.

(Concluded from No. 7, p. 230.)

A CASE OF ADENO-FIBROMA OF THE ANTERIOR WALL OF THE BLADDER.

DR. FRANCIS R. HAGNER, of Washington, D. C., presented this specimen. He said he had never seen a case like it before. L. R., aged sixty-eight, had suffered with prostatic obstruction, with increasing severity, for five years. There was one quart of residual urine. The prostate was small and firm. Several diverticula were seen in the bladder, and also a small stone. On doing a perineal prostatectomy the stone could not be removed, and the bladder was opened from above. On examining the anterior wall of the bladder with the finger a tumor was felt to the right of the median line, under the mucous membrane. The pathological report showed it to be an adeno-fibroma, showing probably a beginning carcinoma. The peculiar feature was the location of the tumor under the mucous membrane.

THE OPERATIVE TREATMENT OF TUMORS OF THE BLADDER

DR. LOUIS E. SCHMIDT, of Chicago, read this paper. An essential difference should be observed in dealing with benign and malignant tumors. The former should be approached from the inside of the bladder, the latter from the outside. In removing benign tumors two methods were used, the endo-vesical, by means of the cystoscope, and by suprapubic cystotomy. The first of these required special skill on the part of the operator, and would not become popular with general surgeons. In the second method, curved scissors should be used in removing the tumor, and ligatures placed as the tumor was removed. The common cause of failure in removing papillomata was because one large tumor was removed, while one or more smaller ones were left. The closed bladder should be suspended to the abdominal wall. In removing malignant tumors the tumor should first be located with the cystoscope, and then approached from the outside of the bladder through a suprapubic incision. The usual method of opening the bladder and hunting for the tumor was condemned. After making the incision, the prevesical fat should be stripped up so that the bladder would be exposed. A few guy-ropes should be fastened to the bladder. The entire bladder should he denuded of its surroundings. A flap of fatty tissue should be turned up over the exposed peritoneum to prevent infection. Any operation that did not remove more than one third of the bladder should be followed by closure of the viscus. A permanent catheter should not be used. The choice of anesthesia in these operations was of considerable importance. He used gas and had found that the patient urinated without the use of a permanent catheter. He had had several cases in which more than two thirds of the bladder was removed, and in which the function was complete after operation. Cystoscopic examination would usually show whether the tumor was benign or malignant. Suspicious ones should be treated as malignant. The operation was justified in malignant cases if it gave only two or three years of comfort. Dr. Schmidt summarized as follows: All benign tumors should be approached from the inside. All malignant tumors should be approached from the outside of the bladder. In all cases in which the loss of substance is not too great the bladder should be completely sutured after the removal of the tumor. The use of the permanent catheter following operations on the bladder should be abolished. All bladders following operation should be kept under constant cystoscopic observation. Gas anesthesia should be used in bladder work.

ELECTION OF OFFICERS.

The following officers were elected: President, Dr. Harvey G. Mudd, of St. Louis; Vice-President, Dr. John van der Poel, of New York; Secretary, Dr. E. L. Keyes, Jr., of New York; Members of Council, Dr. Hugh H. Young, of Baltimore, and Dr. F. Tilden Brown, of New York.

THURSDAY, MAY 9, THIRD DAY.

JOINT SESSION OF THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS AND THE AMERICAN GYNECOLOGICAL SOCIETY.

SOME CONGENITAL VARIATIONS OF THE KIDNEYS AND URETERS, IN REFERENCE TO THEIR DEVELOPMENT AND SURGICAL IMPORTANCE.

DR. GEORGE S. HUNTINGTON, of New York, exhibited an interesting collection of lantern slides illustrating these conditions.

THE RADIOGRAPHIC DIAGNOSIS OF RENAL LESIONS.

DR. LEWIS GREGORY COLE, of New York, read this paper, and showed numerous lantern slides. He divided the rays into direct, indirect and secondary. With the indirect and secondary rays cut off it was possible to show not only the bony detail, but also muscles, fat, connective tissue and even the blood in the veins. With proper technique he believed any variety of renal, ureteral or vesical calculus of sufficient size to justify operation could be diagnosticated. This statement was made after experimenting with the softest calculus that could be found. Enteroliths, osteoplaques, phleboliths and calcified glands often made a diagnosis difficult, particularly in the case of suspected ureteral calculus. Exploratory operation sometimes failed to find stones when they were actually present, or some were found and others left, and for these reasons he thought the x-ray was more reliable. Catheterization of the ureters was better in ureteral stones than in renal stones, but was not certain in either. A combination of catheterization with a styletted catheter and the x-ray was the best method of showing ureteral calculi, the pictures being made at different angles.

SPECIMENS AND ILLUSTRATIONS OF RENAL LITHIASIS, PYONEPHROTIC STONE KIDNEY, AND RENAL TUBERCULOSIS.

DR. CHARLES H. CHETWOOD, of New York, presented this collection of specimens and illustrations.

THE DIAGNOSIS AND TREATMENT OF CALCULI IN THE LOWER END OF THE URETER IN THE MALE.

DR. HUGH H. YOUNG, of Baltimore, said that a few years ago, while taking a trip through the West Indies

he met a very interesting case on shipboard. One year previously the patient had had symptoms of renal colic, but now began to suffer with a peculiar set of symptoms. He had a dull, aching pain in the rectum, pain in the bladder at the end of urination, severe pain on ejaculation, and pain occasionally radiating up to the kidney and sometimes to the testicle. He was told that he had a stone engaged in the lower end of the ureter, which projected into the bladder, irritating it, obstructing urination, impinging upon the seminal vesical, giving the ejaculatory symptoms, and close enough to the rectum to give pain in that organ. He was cystoscoped and the stone was seen sticking out of the orifice of the ureter. The stone was removed and the patient recovered. Since then Dr. Young said he had studied more thoroughly the anatomy of that region, and he thought it was very plain that there was an anatomical explanation for the above group of symptoms. The lower end of the ureter came in contact with the seminal vesicle. The vas deferens hooked around and was very close to it. The rectum lay immediately behind. He had collected 5 or 6 cases showing more or less this group of symptoms in every case. He classified stones in the lower end of the ureter as intravesical, where the stone was projecting into the bladder; intramural, in which the stone was in the bladder wall; and juxtavesical, in which the stone was immediately behind the bladder and close to it. The second case he saw had a stone in the intramural portion of the ureter. This patient had pain in the bladder, severe pain during ejaculation and severe pain in the rectum when constipated. There was no pain in the testicle. In another case in which the stone was intramural there were frequency of urination, pain during urinating radiating to the end of the penis, and renal symptoms, but no rectal or ejaculatory symptoms. In another case in which the stone was a little farther up than that (2 cm. above the bladder) there was no pain on urination, no ejaculatory pain or pain in the rectum, but there was severe pain in the testicle. The stone was in the ureter where the latter crossed the vas deferens. Three other cases presented very much the same symptoms. The intravesical stones could be removed suprapubically, but in some cases the stone was so high up that it was necessary to do the extraperitoneal iliac operation. This extraperitoneal iliac operation had been done by Dr. Young in 8 cases, and he had found 10 others reported in the literature.

CALCULOUS ANURIA, WITH SPECIAL REFERENCE TO BILATERAL RENAL CALCULUS, AND TO THE SIMULTANEOUS PERFORMANCE OF BILATERAL NEPHROTOMY IN THOSE CASES, AND TO CALCULOUS ANURIA OCCURRING IN PATIENTS HAVING BUT ONE KIDNEY.

DR. FRANCIS S. WATSON, of Boston, read this paper. He laid great stress upon the importance, when doing a nephrotomy, of nephrolithotomy in a case of calculous anuria, of cutting into the second kidney, whether the first kidney was found totally or partially destroyed. If the first kidney was totally destroyed, cutting into that kidney alone would only add shock to an already critical condition. So far as he was aware he was the only surgeon who acted upon this principle. It was very difficult to determine when cutting into a kidney just what its functional ability was, but if the surgeon was at all doubtful as to whether it was capable of sustaining life, the other kidney should be cut into then and there. If the contrary was the case the second kidney should not be cut into. Dr. Watson showed an apparatus which he had devised for patients to wear with renal fistula.

THE VALUE AND METHOD OF MENSURATION IN VESICAL URETERAL AND RENAL WORK.

This paper was read by DR. HOWARD KELLY, of Baltimore, who made a plea for more careful, accurate and scientific methods in the study and recording of cases. He described his methods of measuring the female urethra, bladder and ureters, and of measuring lesions in the bladder. He also described his method of transvesical collection of urine, where for any reason the surgeon did not want to catheterize the other ureter. The diseased ureter was plugged with a large ureteral catheter, the bladder wiped out, and the urine from the other side allowed to collect in the bladder.

SPECIMEN: PUS KIDNEY.

DR. WILLIAM E. MOSELY, of Baltimore, presented this specimen. It was a very large pus kidney, which was supposed to be a multilocular cyst of the ovary until the abdomen was opened. The patient presented the typical appearance of a woman with a large ovarian cyst. The kidney contained seven liters of creamy pus, and a stone was found blocking the upper end of the ureter.

A CONSIDERATION OF THE PATHOLOGY, DIAGNOSIS AND TREATMENT OF ACUTE UNILATERAL SEPTIC INFARCTS OF THE KIDNEY.

This paper was read by DR. GEORGE EMERSON BREWER, of New York. One year ago he had presented a paper before the Chicago Medical Society on "Some Observations on Acute Septic Infarcts of the Kidney." Since the publication of that paper a number of successful cases had been reported to the New York Surgical Society, and the criticism made that nephrectomy was not always necessary. In his former paper he was dealing only with the very acute cases, in which nephrectomy was the only measure to save life. The mild types frequently recovered spontaneously. The symptomatology of the milder types was obscure, and the diagnosis was usually not made. A typical case would show the usual symptoms: A female, aged twenty, had double femoral fracture. After three weeks of treatment, she suddenly became violently ill, with symptoms suggesting an attack of acute grippe. The temperature was 104°, pulse accelerated, pains in the extremities and back, tenderness over the right kidney, albumin and some pus in the urine. Exploratory nephrotomy was advised but refused. The symptoms increased in severity. There were now chills, fever, delirium, pain and tenderness in the back. Consent was finally obtained for operation, and the right kidney was explored. The surface of the kidney was found to be covered with deep red spots, and on section the kidney was seen to be full of small abscesses. Some cases closely resembled appendicitis and gall bladder disease. In the severest types nephrectomy should be done. In the milder cases, decapsulation and the opening of cortical abscesses would be sufficient. In the mildest type expectant treatment should be used.

SOME REQUIREMENTS OF "UP-TO-DATE" NEPHRECTOMY.

DR. G. M. EDEBOHLS, of New York, read a paper by this title. In recent years much work had been done in the endeavor to find a reliable method of determining the functional activity of the kidneys, either separately or combined, in advance of a contemplated nephrectomy. Nothing approaching a consensus of opinion had been reached. He considered his method of examining the fellow kidney through a second lumbar

incision the one upon which most reliance could be placed. He advocated decapsulation of the second kidney in these cases to prevent anuria. His conclusion was that no nephrectomy should be done without examining and decapsulating the remaining kidney.

Dr. Caldwell, of New York, showed a number of lantern slides to illustrate the differential diagnosis between calculi in the urinary tract and those bodies outside the urinary tract which might be mistaken for urinary calculi. He agreed with most of Dr. Coles's conclusions, but did not think it was always possible to show a calculus with the x-ray. In the case of certain uric acid calculi, he believed, it was impossible to make a diagnosis. However, no other method was so accurate. He did not sanction the nomenclature used by Dr. Cole in describing the different varieties of rays.

Dr. Howard Kelly, of Baltimore, wanted to know if there was any secret about any part of this x-ray work.

Dr. Cole replied that there was absolutely no secret of success in x-ray work, except the one that Dr. Kelly had, which was attention to the minutest detail from start to finish.

Dr. L. Bolton Bangs, of New York, said he would like to inquire as to the diagnosis and treatment of these phleboliths. When he had found them, without relation to kidney symptoms and therefore without relation to radiographs, he had been puzzled as to their exact location and as to what to do for them. It was possible to remove certain ureteral calculi in the lower end of the ureter by manipulation, with an instrument in the bladder and a finger in the rectum. A case was mentioned in which this was done. He said he wished to inquire of the gynecologists present why kidney infections were more common in women than in men.

Dr. F. Tilden Brown, of New York, spoke of the importance of catheterizing the ureters, and particularly of the importance of employing the styletted catheter combined with radiography. He made a plea for the more general use of these measures. A case was mentioned in which by these measures it had been possible to make out a double ureter, the points of entrance into the kidney, etc. He could not agree with Dr. Cole that a negative diagnosis of stone could be made by the x-ray alone, no matter how carefully and completely the examination was carried out.

Dr. E. B. Cragin, of New York, in answer to the question asked by Dr. Bangs as to the greater frequency of kidney infections in the female than in the male, especially in women who had been pregnant, said it could be explained by the pressure of the uterus on the ureter, particularly the right ureter, due to the position of the uterus in the right oblique diameter of the pelvis, this latter accounting for the greater frequency of infection of the right kidney than the left.

Dr. Francis R. Hagner, of Washington, D. C., reported a case of renal calculus with pyonephrosis, to show the importance of considering the question of renal disease in cases having only bladder symptoms. The patient had never complained of any kidney symptoms, but on operation 30 stones were found in the kidney.

Dr. Howard Kelly, of Baltimore, said an important class of cases in which mensuration was used was cases of hydronephrosis. He collected the fluid and measured it as it came away.

Dr. Latthorn Smith, of Montreal, mentioned a case of a woman who had come to him with what was supposed to be a large ovarian cyst. The abdomen was opened, and it was found to be a large pus kidney containing a number of large calculi. In reply to the question as to why women were more liable to kidney infections than men, he thought there were two reasons, their greater liability to tuberculosis and their greater confinement to the house, predisposing them to the uric acid diathesis and rheumatic troubles generally.

Dr. Cole said if the terms he employed to designate the different varieties of rays had been used before he was not aware of it. He wished to bring the subject before the profession generally as the reason for getting the results shown by Dr. Caldwell and himself. A large amount of indirect rays was the cause of failure.

Dr. Edebohls thought that kidney diseases were more common in women because movable kidney was more frequent in women than in men.

Book Reviews.

Clinical Lectures on Neurasthenia. By Thomas D. Savill, M.D., London. Third (revised and enlarged) edition. 8vo. Pp. xvi, 216. New York: William Wood & Co. 1907.

In the present edition of this work the lectures on diagnosis, pathology and treatment have been enlarged and a new lecture on etiology and prognosis has been added. Some of the errors of the first edition have been corrected, but the author still lacks any thorough knowledge of his particular subject or nervous and mental diseases in general. The need of a third edition, or even of a first edition, is inexplicable.

Surgical Diagnosis. By Daniel N. Eisendrath, A.B., M.D., Adjunct Professor of Surgery in the Medical Department of the University of Illinois (College of Physicians and Surgeons); Attending Surgeon to the Michael Reese and Cook County Hospitals, Chicago. With 482 original illustrations, 15 of them in colors. Philadelphia and London: W. B. Saunders Company. 1907.

Of the writing of many books there is no end. It is four years since the author of this volume produced his useful textbook on Clinical Anatomy. Since then he has been very busy with his writing. To this reviewer his purpose in compiling "Surgical Diagnosis" is not altogether clear. Why did he write this book? He tells us in the first lines of his preface: "A recognition of the necessity of making a correct diagnosis before instituting treatment has prompted me to write this treatise." That bromidic reflection is no stimulus to the unfortunate reviewer in these dog-days. Indeed, the position of a reviewer of books on surgery is a difficult one. Any scribbler is at liberty to review the latest novel of Mr. James, or Mr. Rhodes's History, but the surgical reviewer must be a specially trained person, and, therefore, himself either a rival workman or a friendly fellow-craftsman of him whose book he reviews.

With diligence and temper, however, will this reviewer perform his allotted task, after looking through carefully the octavo of 775 pages before him. The book bears abundant evidence of the toil of the author, and the enterprise of the publishers. The former has taken, in their order, the big and little topics of a treatise on Surgery, and faithfully and laboriously has he dealt with them. Dr. D. L. Schram, who supplies the

chapter on examination of the blood, and Dr. G. Kolischer who writes upon cystoscopy, have abetted the author in the production of this volume.

The book deals with the subject of diagnosis only, — of the diagnosis of those affections which fall properly to the general surgeon. The author seems to have written with fairness and thoroughness, and to have made some study of surgical literature, if one may judge from the numerous familiar paragraphs; but nowhere in the book does this reviewer find proper references to current literature, or to well-known surgical authorities. Steadily for hundreds of pages the writing flows on, serving up to us familiar facts, rarely disguised in a new dress. There are nearly 500 illustrations, mostly photographs,— ordinary, uninteresting. There are a few suggestive skiagraphs, a few colored prints, outline drawings and sketches. The subject of "Surgical Diagnosis" is covered thoroughly; the work is a miracle of the commonplace, and one lays it down at last with his original query unanswered, Why did the author produce it?

The Technic of Operations upon the Intestines and Stomach. By ALFRED H. GOULD, M.D., of Boston. With 190 illustrations, mostly original, several of them in colors. Philadelphia and London: W. B. Saunders Company. 1906.

This is an interesting but curiously uneven book, of which a brief review is not easily accomplished, the good and the second-rate being so constantly commingled. Gould has written an elaborate monograph, addressed directly to the reader, but has adapted throughout a passive, negative and indirect *form* of address, which weakens constantly the force of his argument and exposition. The production is creditable to the publishers and artists, and bears witness to the diligence of the author. There are countless earmarks of the writer's immaturity in a knowledge of constructive technique, and one wishes that he had waited another year before rushing into print with so interesting a mass of material as yet undigested. He should have made a study of correct book-making, but his are common faults and one must overlook them in view of the really beautiful plates and the convenient form of the book.

The author evidently has spent a great deal of time in the laboratory, and his views and statements are based upon experiments upon animals, on anatomical research and an extensive study of surgical literature. He has been fortunate in securing the co-operation of Florence Byrnes, whose beautiful histological drawings illustrate the first chapters of the book, while one recognizes the hand of H. F. Aitken in the careful but somewhat formal and mechanical sketches of gross anatomy, — sketches which, together with those of Miss Byrnes, fill more than half of the 294 pages assigned to the text.

Gould divides his subject into six chapters, and his artists have supplied him with 190 illustrations. Chapter I deals with repair of intestinal wounds and repeats properly enough the well-known views of numerous authors. Incidentally we read in this and subsequent chapters interesting dissertations on Harrington's segmented ring, the best and most satisfactory exposition of that subject hitherto printed. The author deals comprehensively also with repair after the use of the plain suture, the Murphy button and the elastic ligature.

In Chapter II the writer plunges into a discursive essay on suture materials, needles, tying knots, sutures and clamps, — interesting topics, but injected somewhat out of place. Chapter II might better have been reserved for an appendix. It is good, however, and is notable especially for the beautiful cuts with which it is illustrated. In this chapter one reads a description of Gould's useful *reserved mattress stitch*, which is somewhat surprisingly described as "a modification of the Halsted mattress." At the time of writing, this reviewer has re-read Chapter II and compliments the author and artists on the clearness of description and the beauty of the cuts in that chapter.

Chapter III concerns itself mainly with an account of the blood supply of the intestines (Aitken's diagrammatic colored drawing of a section of gut and mesentery, with interlaced arteries and veins, is striking), and the reproduced studies of Monks, on intestinal localization, are as interesting as ever.

Chapters IV and V constitute the pith and marrow of the book. They deal with operations on the intestines and on the stomach and sketch in luminous detail the most approved technique of these operations. As usual, the illustrations are the notable features. Gould has been able to secure a few of Miss Byrnes's admirable anatomical sketches for these chapters, though the bulk of the illustrations come from the hand of Aitken. It seems a pity that one artist could not have supplied and made uniform all of the illustrations. Such a criticism may sound captious, but Gould's book is so ambitious, and in many respects so unique as a collection of illustrations, that one regrets every failure to attain perfection. The pictures show sundry methods of resecting, anastomosing, stitching, grafting omentum and supplying mechanical devices. Perhaps the most interesting subject with which the author deals in Chapter V is McGraw's colostomy with the rubber ligature. Chapter VI is as interesting as Chapter V. The admirable description and illustrations are satisfactory, especially the illustrations of Finney's "pyloroplasty." Nowhere else have we seen so lucidly demonstrated the difficult steps of Finney's somewhat obscure operation.

One cannot assert that Gould's book should be a *vade mecum*, the indispensable companion of every surgeon, but certainly it will be a useful addition to the medical student's library and to the Laboratory of Surgical Research.

This work is dedicated to the eminent teacher and distinguished surgical veteran, Professor Charles Burnham Porter, of the Harvard Medical School.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 22, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

SCHOOL FOR SOCIAL WORKERS.

IT becomes increasingly evident that medicine on its practical side is coming nearer and nearer to the various social problems of the time. It follows as a natural consequence that in order to accomplish the best work in relation to social conditions which come within his scope the physician should have a somewhat special training. We have no doubt if the present development goes on, and there is no reason to question that it will not, that an opportunity will be offered a certain number of medically trained men to devote their best energies to the elucidation of social problems quite apart from the ordinary practice of medicine. It has been amply demonstrated, particularly during the last few years, at the Massachusetts General Hospital, that the opportunities for benefiting the poor lie far beyond the mere administration of drugs and other remedial measures. The success of this social work at this institution has been clearly indicative of the necessity for its wider recognition.

We are glad, therefore, in this connection, to call attention to the School for Social Workers in Boston, maintained by Simmons College and Harvard University, which begins its fourth year Oct. 1.

It is of general interest, together with like schools in New York, Chicago and London, as a new departure in the field of education; for these schools were opened, a few years ago, to help answer the call for good workers in charity, correction, neighborhood work and kindred forms of social service. The demand for such is greater than the supply. And the demand is increasing the demand.

The schools do not mean that the body of knowledge, the general principles and technique, on which effective social work is built, is now very extensive or difficult to learn, or that such work is to be wholly done by the so-called professional, but they show a growing appreciation in this field of human endeavor, as in all fields, of the value of experience, and of the economy of real preparation. The more professionals there are, workers of experience, who give their time and thought effectively as leaders, the greater should be the number of others who are doing and giving, some much, some little, but all helpfully, in all sorts of ways of social service.

The Boston School, for example, had twenty-seven students the first year. Last year there were thirty-eight. Nine of these were men. The men were registered in Harvard University, some of them being candidates for degrees, toward which the work in the school counted. The women were registered in Simmons College. One of them completed in the school the requisite courses for the degree of Bachelor of Science. Of the thirty-eight, ten were persons of considerable experience in some form of social service. Thus are brought together men and women, students and workers, to consider from various points of view the problems which are of concern to all who would better social conditions. The course is one academic year. For exceptional reasons, it may be taken in two years. As a preparation for it, women may take a year as special students in Simmons College, studying biology, hygiene, psychology, ethics, economics, etc. But there are no requirements for admission to the school beyond evidence that the student will profit by the opportunities offered. Most of the students give their working time to the course; some give part time.

The instruction is largely by conference, helping students to think for themselves. There is study of, and reports on, selected literature. Lectures are given and special problems are presented by persons of exceptional experience in particular activities. Some very practical work with selected agencies, under skilled direction, is required. The topics of the carefully arranged program, following one another in logical order and being knit together, include the aims of social service; leading principles underlying all social effort; improvement of general conditions of living by community and voluntary action; neighborhood improvement in city and country; treatment of needy families, of persons out of their own families, of the offender and delinquent.

The announcement is now made that the school will conduct this coming year, and probably in the

future, some research work in subjects touching charity and social advance. This work will be done, under skilled direction, by chosen persons, perhaps advanced students with practical experience.

There is evidently opportunity here for a properly qualified medical man to equip himself with a knowledge of modern methods in charity and to bring to the general work the much needed acquaintance with medical matters, and conditions of disease, which so frequently lie at the basis of social problems. The time seems ripe for the medical profession in general, and for certain selected members of it in particular, to extend the range of their activities into a scientific study of social problems to a degree not hitherto attempted. The School for Social Workers which has been established in this city would, no doubt, welcome one or more qualified physicians to its classes in order that the social problems may be approached and discussed primarily from the medical standpoint as well as from the standpoint of other interests and professions.

ACCURACY OF THOUGHT IN MEDICINE.

Each year at the meeting of the larger medical associations several general addresses are delivered. At times the subjects selected deal with some limited phase of medical science. More frequently broader relations of medicine are considered. In the latter there is of necessity often a repetition of subjects, rarely a reiteration of subject matter. Old truths are driven home in new forms, and well known facts go to make up a timely address. Such was the recent address in medicine of W. Hale White before the British Medical Association, a "Plea for Accuracy of Thought in Medicine." It was timely, not because there is less accuracy now than formerly, for such is not the case, but because the examples used by the speaker will impress on almost every medical man that there is yet much inaccuracy in medical thought. Moreover, through the address, beneath a superficial spirit of apparent pessimism, runs a broad undercurrent of optimism, an optimism that should inspire every worker in medicine to inquire, to observe, to experiment, for the field of possible discovery is shown still to be a broad one, and many facts which we accept without a critical thought should still be doubted, then submitted to critical observation and experiment with the confident expectation of the discovery of new facts. In these thoughts there is undoubted optimism and a suggested reaction against a possible unfortunate tendency of medical science to regard its problems as now highly specialized and only capable of solution by the trained worker in the well equipped laboratory. There are many problems of course for the latter, but the average medical man can still do much toward the general advance of medicine should he keep in mind some of the suggestions of Professor White, and for these reasons the address should be widely read.

In discussing diagnosis, Professor White says: "We should not make a diagnosis which implies a cause unless we have grounds from the previous experience of ourselves and others for prophesying what will be found at post-mortem examination. . . . I quite admit that we shall often have to say we do not know, and no doubt our diagnosis will sometimes be wrong, but at any rate our reticence and our mistakes will not retard, but will rather advance progress in medicine. . . . The primary duty of a physician is to find out what is the matter with his patient. Proper treatment can only be secondary to that. . . . Another reason for incorrect treatment is that many say, 'You must do something.' I can never see the reasonableness of this. The very fact that the medical man does not know what to do is actually used as a reason why he should do something. Surely it is the very reason why he should do nothing, for he may well do more harm than good." Certainly there is much common sense in this.

The pitfalls of deductions based on statistics and the necessity of a real knowledge of statistics are forcefully pointed out. In this respect both physician and surgeon are likely to err. The thoughtful reader of some of the examples used in this connection hereafter will and should consider most carefully his data and the contingent circumstances before venturing any conclusion. If this be done, fewer incorrect impressions will be accumulated on which to base principles that will long stand supported by the authority of time and well known author unless some inquiring skeptic prove their falsity.

SEVENTH INTERNATIONAL ZOOLOGICAL CONGRESS.

During this week the seventh International Zoölogical Congress is meeting in this city and, as was expected, has brought together a large number of distinguished zoölogists from various parts of the world. The meetings are for the most part being held in the buildings of the new Harvard Medical School which lend themselves

peculiarly to such a gathering in which various sections are holding meetings at the same time, necessitating the use of many rooms for the reading of papers. Every effort has been made by the local committee to render the stay of the visiting men of science and their families enjoyable. To this end many excursions and entertainments have been planned, and there will be opportunity, therefore, not only to attend the various scientific sessions, but also to visit many points of historical or of educational interest in the vicinity of Boston. The general meetings of the congress, which have been very largely attended, are being held in Jordan Hall at the New England Conservatory of Music.

At the first general meeting of the congress, after introductory remarks by Prof. Alexander Agassiz, an address was delivered by Prof. R. Hertwig, of the University of Munich, on "Newer Problems in the Study of the Cell." This was, perhaps, the most notable contribution of the meeting, but many others, both from American and foreign investigators, will prove of much value as indicating the progress of science in the zoölogical field. An address by Professor Brooks on the subject, "Are Heredity and Variation Facts?" and the discussion of Entomology in its practical aspects by Dr. L. O. Howard will undoubtedly excite a high degree of interest. The section meetings are filled with papers chiefly of scientific interest, and it is not to be questioned that during the week will be presented the latest investigations in a wide range of correlated subjects.

These meetings, which are begun in Boston, are to be continued in Philadelphia, Washington and New York, so that the visiting zoölogists will have gained an adequate idea of the scientific foundations in the various Eastern cities, and, incidentally, will have learned something of American life. It is a matter of interest that such a congress should be held under the auspices of a medical school as is being done in Boston. It indicates the gradual integration of the natural sciences in conjunction with the development of specialism, and is altogether a hopeful sign for the future.

MEDICAL NOTES.

SCARLET FEVER IN CHICAGO. — According to the *Bulletin* of the Chicago State Board of Health, special attention has been paid to scarlet fever during the last twelve months, because fifty years' record of this disease in the city indicates that one of its characteristic epidemic waves has set in, which may not entirely subside for four or five years to come. These epidemic waves are due to accumulations of susceptible individuals during the periods of decreasing frequency of this disease, as is well shown in the diagram. Previous to 1876 the epidemics averaged six years apart, and the death-rate in 1859 reached the high point of 27.2 per 10,000 population. The epidemics gradually declined in virulence till that of 1876–7, with a rate of 19.05. The outbreak in 1879 gave a rate of only 7.92 and succeeding epidemics have shown a steady decline till 1906. The years 1896 and 1905 had a minimum of scarlet fever, with a rate of only 0.39 per 10,000 of population. Owing to the comparative freedom from the disease for several years, a large crop of susceptibles has accumulated, with the resulting epidemic of the past year. In 1906 the rate rose to 2.41 and January to June, 1907, showed a further increase to 4.45, a rate which has not been exceeded since 1884. Last month the rate returned to 2.38.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Aug. 21, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 27, scarlatina 29, typhoid fever 13, measles 10, tuberculosis 35, smallpox 0.

The death-rate of the reported deaths for the week ending August 21, 1907, was 20.82.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, Aug. 17, 1907, was 220, against 228 the corresponding week of last year, showing a decrease of 8 deaths and making the death-rate for the week 18.83. Of this number 120 were males and 100 were females; 213 were white and 7 colored; 146 were born in the United States, 71 in foreign countries and 3 unknown; 36 were of American parentage, 163 of foreign parentage and 21 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 31 cases and 1 death; scarlatina, 24 cases and 0 deaths; typhoid fever, 11 cases and 1 death; measles, 19 cases and 2 deaths; tuberculosis, 43 cases and 25 deaths; smallpox, 1 case and 0 deaths. The deaths from pneumonia were 6, whooping cough 1, heart disease 17, bronchitis 3 and marasmus 1. There were 18 deaths from violent causes. The number of children who died under one year was 70; the number under five years, 86. The number of persons who died

over sixty years of age was 33. The deaths in public institutions were 75.

There were 2 cases and 3 deaths reported from cerebrospinal meningitis during the week.

Enlargement of Mary Fletcher Hospital, Burlington, Vt. — Additions to the Mary Fletcher Hospital at Burlington are being made at a cost of $100,000. Two new wings are to be built, stretching east and west from the main administration building, each 110 by 50 feet. It is proposed to devote one of these wards to surgery and the other to medical cases.

Gift to Worcester, Mass., Memorial Hospital. — Through the generosity of Mr. Charles H. Morgan and Mr. George L. Newton the Worcester Memorial Hospital has received funds to the amount of $80,000 for the erecting of new wards. Mr. Morgan's gift, of not over $40,000, is to be used for the construction of a maternity ward to be known as the Rebecca Morgan Memorial Ward. The remaining $40,000, given by Mr. Newton, is to be used for a building for private patients.

NEW YORK.

A Serum for Meningitis. — The newspapers report the apparent success of a new serum against cerebrospinal meningitis, devised by Dr. Simon Flexner, of New York, director of the Rockefeller Institute for Medical Research, in an outbreak of the disease at Castalia, Ohio. The serum was employed on the advice of Dr. George T. Ladd, of Cleveland, who is a member of the faculty of the Western Reserve Medical College and on the staff of the Lakeside Hospital. Whether it was given in other cases is not stated, but in three cases, in which the ages of the patients were respectively 23, 16 and 3 years, and which in the opinion of the local profession would inevitably have proved fatal without it, recovery followed the use of the serum. Dr. Flexner has been in Europe this summer, but is expected back very shortly.

Analysis of Food Products. — In the monthly bulletin of the State Health Department, given out on August 6, it is announced that the most recent analyses of food products, made for the purpose of determining whether preservatives are employed, show a considerable improvement in this respect. Out of nine samples of canned meats examined, but one contained a preservative. Of twenty-five samples of bottled beer examined, several contained sulphites, three or four, fluoric acid, and two, salicylic acid.

Fatal Poisoning by Cocaine. — A case of fatal poisoning by cocaine employed as a local anesthetic occurred in the practice of Dr. G. Lenox Curtis, a well-known specialist, on Aug. 15. The operation for which the cocaine was employed was the removal of tonsils and adenoids, and the patient was the seven-year-old son of Thomas T. Whiting, of Burlington, Vt., an intimate friend of Dr. Curtis. The operation was successfully performed and the boy appeared to be in excellent condition for half an hour afterward, when sudden collapse occurred, and the utmost efforts of Dr. Curtis and a colleague were unable to avert the fatal issue.

Arrest of President of Woodbury Dermatological Institute. — In order to test the new medical law enacted by the recent Legislature, Robert Buggeln, president of the Woodbury Dermatological Institute, has been arrested at the instance of the Public Health Defense League, and charged with violating a section of the law which provides that any person not a registered physician who shall advertise to practise medicine shall be guilty of a misdemeanor. Buggeln was arraigned in the Jefferson Market Police Court, and after the usual formalities was paroled in the custody of his lawyer. The proceeding begun by this arrest is of wide scope, and if the Health Defense League is successful in its contention, the decision of the courts will affect not only the practice of medicine by corporations of quack doctors and of patent medicine companies in the state, but also that of trust and fidelity companies with medical features, which undertake the business of attorneys. John S. Cooper, counsel of the League, is of the opinion that it does not matter whether a corporation employs physicians or not, and that persons who accept treatment under them are not protected by that provision of the law which makes all communications between physician and patient confidential. In Pennsylvania it has been determined that a corporation entirely composed of physicians may practise medicine, but he believes that this contention is not in accord with the spirit of the New York law. In support of this view Mr. Cooper quotes the opinion of the Appellate Division of the New York Supreme Court by which a lawyer, Abraham Kaffinburg, was disbarred. By this decision it was declared that when an attorney took his oath of office he became part of the machinery of justice in the state, and that his permission to practise was a personal license which he could not delegate to others. This

doctrine, he maintains, must be applied with equal force to physicians. Under the Pennsylvania decision, should a corporation of physicians be formed, it is evident that any member of such corporation could transfer, with his stock, all of the privileges and duties enjoyed and performed by him to a layman. But, taking the opinion of the Appellate Division in the Kaffinburg case, which was affirmed by the Court of Appeals, in connection with the section of the law under which Buggeln was arrested, it would seem evident that no corporation, however formed, could practise medicine in the State of New York, or exercise the fiduciary relation which lawyers and physicians exercise, any more than a corporation could exercise the relation of a clergyman or priest. Another part of the section under which Buggeln's arrest was made provides that no one can conduct a medical practice under the name of another, and it has been established as a matter of fact, that John H. Woodbury, who organized and for a considerable time managed the Woodbury Institute, is no longer connected with that concern. The evidence which caused the arrest was obtained from the newspaper advertisements and the literature disseminated by Buggeln.

MEDICAL RECORD.
JULY 27, 1907.

1. *COLEY, W. B. *Inoperable Sarcoma. A Further Report of Cases Successfully Treated with the Mixed Toxins of Erysipelas and Bacillus Prodigiosus.*
2. DICKINSON, G. K. *Through Physiology to Pathology in Complications of Gall-Bladder Disease.*
3. *BREW, J. *Reinfection with Syphilis; Report of a Case with Hereditary Syphilis in the Child.*
4. GALLANT, A. E. *The Long-Waisted Woman and Her Movable Kidney.*
5. ROSENWASSER, A. A. *Apomorphine in Acute Alcoholism; a Plea for Its More Extensive Employment.*

1. Coley makes a report of forty-two cases treated by himself for inoperable sarcoma with mixed toxins of erysipelas and *Bacillus prodigiosus*, with twenty-six patients remaining well after a lapse of from three to fourteen years since the treatment. The author at first used the germs of erysipelas alone, but later found that the combination of the two germs had a better effect, as well as less danger, than the single germ. Later he used only sterilized cultures containing both the toxins and the bodies of the bacteria, since this mixture produced a much more decided effect than weaker ones. The curative action is brought about by increased leucocytosis and coagulation necrosis. The treatment should begin with not more than one-quarter minim diluted with boiled water. If the tumor is highly vascular, begin outside the tumor. When given in the tumor increase the dose by one-quarter minim, and by one-half minim if remote from tumor, until desired reaction is obtained. The tumor soon becomes smaller, more movable and less vascular. Its action is both local and systemic, and the systemic effect alone may be used successfully in cases that are inaccessible. The author finds about one hundred successes by other physicians by this method. It may be used as a prophylactic against recurrence after operation. A new field is in the injection of cases in which the amputation of a long bone appears necessary, and by its use the amputation may be avoided. The author gives a detailed description of twelve of his successful cases.

3. Brew describes a case in which there was every reason to believe that syphilis had existed and been cured and a reinfection had occurred. Most syphilographers at the present day agree in saying that such a cure and reinfection are possible, although rare. The patient described was treated carefully for an undoubted attack of syphilis, from which he recovered and remained without any syphilitic manifestations for fifteen years. He was then treated for a hard chancre followed by a macular eruption and sore throat. Marrying then, a syphilitic child was born to the couple, although the mother showed no evidences of ever having had the disease. The manifestations of the second attack could not have been tertiary in their nature.

6. *ALLEN, A. H. *Phagocytosis, etc., in Sputum, as a Measure of Resistance in Tuberculosis.*
7. BRANDEIS, J. W. *Consanguinity: a Factor in Immunity to Scarlet Fever.*

1. Crile and Cole performed bilateral nephrectomy upon 10 dogs, 5 of which were kept as controls and 5 of which were bled and transfused forty-eight hours or more afterward. The transfused dogs lived on the average longer than those not transfused, but not longer than dogs subjected to bilateral nephrectomy by other writers.

6. Allen has made studies of phagocytosis of tubercle bacilli in sputum with a view to determining whether or not the intracellular position of tubercle bacilli gave any evidence of the resistance of the patient. His results were in the main negative, except for the somewhat unexpected finding that cases treated with tuberculin showed less phagocytosis than those which had not received tuberculin. It is made clear that studies of phagocytosis in sputum are subject to error from many sources.

3. Risley urges surgical treatment not only in the inflammatory types of glaucoma but in the so-called chronic or non-inflammatory types, when the gradual onset and lack of severe symptoms make early diagnosis difficult. In such cases the beginning is marked only by slight transient exacerbation of dimness of vision, with some discomfort, pain or sense of fullness in the eye or peri-orbital region. Recurrences occur with increasing frequency, and the impairment of vision becomes permanent. The eyes become injected, the cornea steamy, the tension of the eyeball somewhat increased, perhaps with cupping of the optic nerve. In such cases an early iridectomy may do much to check the progress of the disease. The technic of iridectomy is important to the success of the result. The difficulties encountered in the late stages of the disease are largely to blame for the failures reported in such cases. The steps of the operation are described in detail.

6. In a fully illustrated article Kolischer and Schmidt lay down the rules for the operative treatment of tumors of the bladder, the essential points of which are substantially as follows: First, benign tumors should be approached from the inside, malignant tumors from the outside of the bladder. In the endovesical operation on benign tumors the authors prefer the cystoscope of direct view, though when the growth is located at the vertex of the bladder, which is extremely rare, the so-called long wire loop of Nitze's operative cystoscope should be employed. In the operation by incision, the suprapubic is the route to be followed and the fundamental principle of the operation is that it should be conducted with one object always in view, *i. e.*, the complete closure of the viscus after the tumor is removed. A liberal incision through the anterior wall is absolutely necessary. The technic of both methods is given in detail. In case of malignant growths, the authors emphasize the importance of a topographic diagnosis of the tumor before operation and a free exposure of that part of the bladder, which is to be in the field of resection, so far as possible, and attempt should be made to reform the bladder after operation for malignant tumors, and it is remarkable how small a remnant will sometimes suffice to form a serviceable organ. When this is not possible, the best method, they say, is to establish permanent kidney fistulas. Kolischer and Schmidt believe that it is practically always possible to determine the character of a bladder tumor before operation; any one of experience in cystoscopic diagnosis can recognize a benign growth, and doubtful ones are to be considered and treated as malign. Nitrous oxide anesthesia should be the one chosen in all cutting operations. Besides its safety as regards the heart, it has the advantage that the patient returns to full consciousness immediately after the operation, thus affording better chances for natural micturition, early breathing exercises and administration of food and drink. A constant cystoscopic surveillance should be maintained over any bladder that has ever been operated on for tumor. The permanent catheter, they say, should be absolutely done away with.

11. Bulkley begins his article with a good general summary and classification of the causes of itching. These he divides under three headings: external causes, notably mechanical irritations, toxic agents, climatic influences, vegetable and animal parasites; idiopathic causes, neurotic and senile; and constitutional causes, notably autointoxication and constitutional skin diseases, such as eczema. These causes must be detected and removed if possible before treatment can be successful. Unsuitable underclothes must be changed, ivy poisoning prevented, extremes of heat and cold guarded against and scabies or pediculosis overcome. Particularly in neurotic and autotoxic cases constitutional treatment is important. Diabetes must be treated if present, and digestive abnormalities must be arrested. Tonics, such as iron, arsenic and strychnine, are of value. As for analgesics it is well to remember that opium and morphine are apt to aggravate the trouble; trional may do the same. Veronal on the other hand is of great service, also chloral, bromide and cannabis indica. In rare cases a few whiffs of chloroform may be used to produce insensibility until other measures can have their effect. Locally the avoidance of irritants and the prevention of scratching are of prime importance. For children a pillow case is an excellent means of restraint, the head being put through a hole made in the closed end and safety pins between the arms and the body and betwee nthe legs effectually controlling movements of the limbs. Of external applications carbolic acid stands pre-eminent. This is best used in the following formula: ℞. Acid, carbolic, ʒss–ʒj, pulv. calamin prep. ʒi, zinci oxidi ʒii, glycerin. ʒiii, aqua calcis ʒi, aquæ rosæ ad ʒiv. Ichthyol in from 10% to 20% solution in water or in oil is of value. Of ointments carbolic acid, the most efficient, is as follows: ℞. Acid carbolic gr. xx–xl; lanolin ʒi; boroglycerin ʒiv; ung. aquæ rosæ ʒiii; or on unbroken skin: ℞. Chloral hydrate and gum camphor each ʒss–i, compound lanolin ointment ʒi. Glycerite of starch may be substituted for the fatty base of ointments. Tar and oil of cade are also useful. [F. W. P.]

1. Halsted's article treats of the results of removal of or injury to the parathyroid glands, and the treatment of the disorder by feeding with the parathyroids of animals. A considerable number of cases of tetany have been reported following operations for goiter. One such case, described at length, fills a large part of this paper. It is known that during the operation the right inferior parathyroid was injured; following the operation the patient at once began to seem restless, and on the seventh day began to have periodic spasmodic attacks. Parathyroid feeding seemed to give marked relief, the fresh glands appearing to be more efficient than dried preparations. Experiments are reported in which parathyroids of an animal have been transplanted into the animal's spleen. In human patients Halsted has several times transplanted parathyroids into the opposite lobe of the thyroid when their nutrition has been imperiled during operation for goiter. In conclusion the danger of tetany as a result of operations upon the thyroid is reiterated, and certain directions are given for the avoidance of injury to the parathyroids.

2. MacKenzie proposes the terms "auricular venous pulse" and "ventricular venous pulse," to replace those of normal or negative venous pulse and pathological or positive venous pulse hitherto employed. A visible venous pulse may be present in apparently good health, or absent in severe cardiac failure. It sometimes appears temporarily in conditions of debility; it is possible that back flow from the auricle depends upon relaxation of the muscle band described by Keith as normally by its contraction shutting off the auricle from the superior vena cava. It is probable that the fibers controlling the tricuspid valve may also relax, permitting tricuspid regurgitation. MacKenzie gives evidence to show that tricuspid regurgitation is of more frequent occurrence than American physicians recognize. He analyses tracings of jugular pulsations which show three waves in each cycle: the auricular wave in the auricular systole, exaggerated in cases with marked auricular venous pulse; the carotid wave which he believes to be merely the transmitted pulsation of the carotid artery; and the ventricular wave, normally small, but very prominent in cases with the ventricular, the so-called pathological or positive venous pulse. MacKenzie believes that venous pulse of the auricular as well as of the ventricular type is caused by tricuspid regurgitation, and shows tracings of cases where, according

to the degree of compensation, the jugular pulse alternated between the two types with curves indicating the gradual transition between the two during the periods of change. He believes that the auricular pulse is seen when a slight tricuspid regurgitation has led only to slight overfilling of the auricle before the auricular systole, whereas the ventricular venous pulse is due to direct regurgitation of blood from the tricuspid valve to the jugular vein.

3. Von Eberts and Hill describe their technic in preparation and administration of bacterial vaccines, and report selected cases of brilliant results. In their work they have followed closely the methods of A. E. Wright, controlling the dosage by the opsonic index. Cases where the treatment was followed by recovery comprise the following conditions: tuberculous ulceration of the bladder; lupus; tuberculous arthritis; tuberculous cervical adenitis; furunculosis; carbuncle; suppurative periostitis; multiple abscess; acne indurata; gonorrheal polyarthritis; and epidemic meningitis.

4. Da Costa, in view of the susceptibility of many diabetics toward bacterial infections, notably toward cutaneous infections and pulmonary tuberculosis, has tested the opsonic index of 22 cases, using the staphylococcus as a representative organism. He finds the index quite constantly low, and especially so in three of the cases in which acetone and diacetic acid were present in the urine. The amount of sugar in the urine bore no constant relation to the diminution of the opsonic index. The article is concluded by a minute description of the technic of determining the opsonic index.

5. Forchheimer defines intestinal auto-intoxication as that condition in which toxins formed in the intestine are absorbed by the organism in which they are produced. These toxins are formed principally if not entirely from albumin and nuclein,. Some albumoses, phenol, indol and the purin bodies, especially the xanthins, are the substances of principal interest. Substances produced by the action of enzymes, albumoses and perhaps the xanthines are formed almost entirely in the small intestine. The bacterial putrefactive products are formed almost entirely in the large intestine. On absorption these substances are in part changed and rendered non-toxic in the liver, lymph glands and other structures, and in part they are excreted by the kidneys. The amount of toxic bodies formed depends upon the nature of the food, the time that it remains in the colon and the character of the processes within the intestine, some pathological modifications of which may be of more importance than is now understood. Clinically 77 cases believed to have intestinal auto-intoxication are analyzed. It is not stated upon what basis the diagnosis was made. The symptoms were extremely various. Riggs's disease of the gums, stomach and intestinal disorders were quite constantly present, especially the last of these. Indicanuria was found in 68 of the 77. Nervous symptoms, especially headaches, were frequent. Circulatory neuroses and myocardial changes were present in a majority of the cases. In closing, the reader is cautioned against making the diagnosis of intestinal auto-intoxication too easily, and expecting it to explain too much in the way of symptoms.

6. Butler's article is the result of his examinations of the heart in 100 healthy children. The outlines and position are carefully recorded as well as a description of the character of the sounds. Murmurs were present in 64 out of the 100, 46 of these murmurs being heard only in recumbency. They were as a rule variable and inconstant, not heard far beyond the cardiac borders, influenced by position and by respiration. Butler considers them to be accidental murmurs, perhaps cardio-pulmonary. He emphasizes the importance of recognizing them as not organic. [F. W. P.]

9. *FLETCHER, W. *Rice and Beri-beri. Preliminary Report on an Experiment Conducted at the Kuala Lumpur Lunatic Asylum.*
10. SANDWITH, F. M. *The Introductory Gresham Lecture.*

6. Forbes-Ross goes into details of the physical causes and characteristics of that area of dullness in pleurisy with effusion found on the sound side of the chest near the spine. The height of this triangle is the height of the fluid on the affected side; it is a triangle in shape because the costo-vertebral groove is widest and deepest below, and narrows and becomes shallow as it ascends, so that the lung on the sound side is able to get nearer to the vertebral column and add its resonance to the dullness transmitted from the diseased side, whereas below it is separated by the thick layer of muscle in the costo-vertebral groove. The writer explains certain exceptions to this rule, especially as applied to empyemata.

7. Alcoholic heart failure is a form of cardiac syncope often met with in certain parts of England where especially large amounts of beer or spirits are taken. The diagnosis is based on the alcoholic history, the absence of valvular disease, of nephritis, and absence of other known causes of cardiac failure. Williamson believes that a valuable diagnostic sign is the loss of the Achilles reflex in these cases while in heart failure due to other causes it is always present.

9. Fletcher conducted an experiment on the lunatics in an insane asylum in Malay during a recent epidemic of beri-beri. A certain number were fed on ordinary uncured rice and others were fed on cured rice. Out of 120 fed on uncured rice 34 suffered from beri-beri and 18 died; of the 34 sufferers 10 had their diet changed to cured rice, and all recovered. Out of 123 fed on cured rice there were only 2 cases of the disease, both of whom had it on entering the asylum. He believes that it is caused directly or indirectly by the use of uncured rice. The causes might be (1) a poison in the rice, (2) deficiency of proteid matter in the rice with nitrogen starvation, or (3) that the rice is not sufficiently nutritious and leaves the body open to infection. 1. Tumors of the jaws are interesting on account of the great multiplicity of the structures which may be involved. The writer first considers epulis, basing his statements on 38 cases admitted to the London Hospital. In excising one of these tumors the teeth in the immediate neighborhood should be removed with the portion of the alveolar arch involved. He then takes up tumors of the jaw itself. Many of these originate he believes from the remains of embryonic tissues, "rests," and he classifies them into two large groups, (1) originating from these "rests," and (2) mostly carcinomatous, originating as a result of chronic iritation of some kind. He considers in detail the pathology of each group as to operation; the mortality is still large, 20% to 30%. A pulmonary ligature of the carotid and laryngotomy he thinks distinctly advisable. The tendency to implicate glands in tumors of this region

has been underestimated. He uses a Gigli saw in cutting through bony parts.

2. Starr in his cleft palate operations uses a thin aluminum plate along the roof of the mouth as a splint to prevent tension. He tried C. H. Mayo's suggestion to use tape for this purpose but found that although it decreased tension it increased the chance of infection and became very foul. The metal, however, has proved very satisfactory. [J. B. H.]

1. Ker and Croom believe that distinctly beneficial results are to be obtained in diphtheria from the use of formic acid, in doses of 5 to 20 minims of a 25% watery solution every four hours. Dosage is graduated more by the severity of the case than by the age of the patient. Convalescence was shorter, and there was a marked diminution in the number of paralyses.

6. Bullmore and Waterhouse have studied the blood in 24 cases of rheumatoid arthritis and conclude that anemia is always present. The leucocytes are normal in number with the normal differential count. In a few cases myelocytes were found. [J. B. H.]

1. By various modifications of the mode of infection and of the bacilli used, Marmorek has been able to change at will the course of tuberculosis in guinea pigs. Bacilli of weak virulence can be obtained by using for injection the heart's blood of animals suffering from severe tuberculosis. The subcutaneous injection of such blood causes a local tuberculous abscess, while the intra-arterial, intravenous and intraperitoneal route does not result in infection. If, however, these weakened tubercle bacilli were "activated" after introduction by means of repeated tuberculin injections, infection did take place, and contrary to the usual course the lungs were involved early. Marmorek was even able by this method to produce cavities in the upper lobes following intraperitoneal and intravenous inoculation. The early localization in the lungs therefore depends, according to him, on the reciprocal relations between virulence of the organism and resistance of the body tissues. The question of hereditary predisposition to tuberculosis was approached in the following way: the young of tuberculous guinea pigs were subjected to inoculation with the before mentioned blood containing bacilli of low virulence, and killed at the end of several months. These animals in fact showed lesions of tuberculosis, which were absent in the controls. But it was necessary that the mother should be in an advanced stage of tuberculosis at the time the litter was born. The last part of the article deals with Marmorek's anti-tuberculosis serum. Animal experiments show that it will prevent infection if injected soon after inoculation with a dose of tubercle bacilli sufficient under other circumtances to produce the disease. The clinical value of the serum for man he claims is established for surgical forms of tuberculosis; the rectal method of administration is preferable because symptoms of the "serum disease" are avoided thereby, *i. e.*, fever, rashes, inflammation about the point of injection. For pulmonary tuberculosis he has provided a serum made by immunizing horses against, first, the tubercle bacillus, and later, the streptococcus. The exact status of this serum must be left to the future to decide.

4. Iodofan is a substitute for iodoform with the formula $C_6 H_3 I (OH)_2 . H CO H$. When brought in contact with wound secretions it splits off formaldehyde iodide. Piorkowski's experiments show that it is feebly bactericidal, but exerts a marked inhibition on the *growth* of bacteria. It also has a very prompt deodorizing action, which is much greater than that of either iodoform or formaldehyde. [W. T.]

4. *COENEN, H. *The Development of the Theory of the Basal-Cell Carcinoma.*
5. MINOR, L. *The Frequency of Quinquaud's Phenomenon in Drinkers and Non-Drinkers and in Nervous Diseases.* (Concluded.)

1. The refraction-coefficient of the blood serum, as Reiss has shown, corresponds very closely to its albumin content. The procedure is adapted for clinical purposes, requiring only a few drops of blood and little time for the determination. It does *not* vary as the number of red corpuscles. Engel reports the results of measurements with the refractometer in a variety of diseases. The lowest values, far below the normal, were found in parenchymatous nephritis, and are ascribed to hydremia. The coefficient is lowest with edema, but may be quite low in cases without edema. In heart disease with hydrops the values were only slightly reduced, so that the determination may be of diagnostic value under certain circumstances. In diabetes the coefficient was very high in several instances, but this cannot be ascribed with certainty to a high albumin content, for we do not know the effect on refraction of the sugar, acetone, etc., that are present in the serum. In acute infectious diseases the coefficient was reduced during the febrile period; in tuberculosis of the lungs it was normal except in rapidly advancing cases. Fifteen cases of cancer showed a marked hydremia, as judged by the low refraction values. In general low values point to the existence of hydremia, while high ones are more difficult of interpretation.

2. Rautenberg publishes curves showing the normal pulsation of the left auricle, registered by means of apparatus in the esophagus. He finds an elevation corresponding to the auricular systole, followed by another synchronous with the ventricular systole; diastole of the auricle is marked by a sharp fall in the curve. He interprets his tracings quite differently from Minkowski.

3. The interesting work of Ascoli and Izar shows that in healthy persons the intravenous or subcutaneous injection of stable solutions of colloidal silver or platinum produces a marked increase in the N excretion. This increase was found to involve chiefly the uric acid excretion, to a lesser degree that of urea and amido-acids; it began within a few hours and lasted several days. The phosphate excretion was not affected. Administration by mouth or rectum produced no increase of the total N, but a relative increase of uric acid. Sterilizing the colloidal solutions by heat rendered them ineffective as far as the metabolism was concerned.

4. Basal cell carcinoma of the skin includes those cancers which start subcutaneously chiefly on the face, and are derived from misplaced basal-cells of the rete Malpighi. They were formerly called endotheliomata. Coenen, as a result of his researches, believes they are derived from the glandular structures of the skin, the sweat and sebaceous glands, or the hair follicles. They include the so-called rodent ulcers of the face. [W. T.]

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED AUGUST 7, 1907.

PETTUS, H. J., assistant surgeon-general. Granted leave of absence for twenty-six days from August 12, 1907. August 6, 1907.

WICKES, H. W., passed assistant surgeon. Granted leave of absence for one month from August 7, 1907. August 3, 1907.

WILSON, R. L., passed assistant surgeon. Directed to proceed to Fontainebleau, Miss., for special temporary duty, upon completion of which to rejoin his station at New Orleans.

BAHRENBURG, L. P. H., passed assistant surgeon. Granted leave of absence for seven days from July 15, 1907, under paragraph 191, Service regulations.

ROBERTSON, H. MCG., assistant surgeon. Granted leave of absence for five days from July 25, 1907, under paragraph 191, Service regulations.

MULLAN, E. H., assistant surgeon. Relieved from duty at Perth Amboy Quarantine Station and directed to proceed to Ellis Island for duty. August 1, 1907.

WOLLENBURG, R. A. C., assistant surgeon. Relieved from duty at Detroit, Mich., and directed to proceed to Ellis Island for duty. August 1, 1907.

HERRING, R. A., assistant surgeon. Granted leave of absence for one day in July, 1907, under paragraph 191, Service regulations.

PORTER, J. Y., sanitary inspector. Directed to proceed to Fernandina, Mayport, Carrabelle, and Santa Rosa for special temporary duty, upon completion of which to rejoin his station at Key West, Fla.

DELGADO, J. M., acting assistant surgeon. Granted leave of absence for one day in July, 1907, under paragraph 210, Service regulations.

DUFFY, FRANCIS, acting assistant surgeon. Granted leave of absence for six days from August 5, 1907. August 2, 1907.

ELFERS, J. C., acting assistant surgeon. Granted leave of absence for twenty days from August 3, 1907. August 5, 1907.

HICKS, B. I., acting assistant surgeon. Granted leave of absence for twelve days from August 4, 1907. August 5, 1907.

O'REILLY, W. J., acting assistant surgeon. Granted leave of absence for eight days from August 8, 1907. August 5, 1907.

SAVAGE, W. L., acting assistant surgeon. Granted leave of absence for thirty days from August 4, 1907. August 1, 1907.

SCHWARTZ, LOUIS, acting assistant surgeon. Granted leave of absence for one day in July, 1907, under paragraph 210, Service regulations.

SIMONSON, G. T., acting assistant surgeon. Granted leave of absence for ten days from August 5, 1907. August 7, 1907.

WETMORE, W. O., acting assistant surgeon. Granted leave of absence for seven days from July 7, 1907, under paragraph 210, Service regulations.

WATTERS, M. H., pharmacist. Excused from duty without pay for seventeen days from August 3, 1907. August 1, 1907.

MISKIMON, R. R., pharmacist. Directed to proceed to Wilmington, N. C., reporting to the medical officer in command for duty and assignment to quarters. August 3, 1907.

APPOINTMENTS.

DR. RODERICK W. BROWNE appointed an acting assistant surgeon for duty at Norfolk, Va. August 7, 1907.

ROBERT R. MISKIMON, of D. C., and C. Roy Ott, of Ohio, appointed pharmacists of the third class. August 3, 1907.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING AUGUST 17, 1907.

E. P. W. HOUGH acting assistant surgeon. Ordered to Naval Hospital, Annapolis, Md.

A. STUART, passed assistant surgeon. Detached from command of the Naval Hospital, Sitka, Alaska, and ordered home to wait orders.

C. C. GRIEVE, passed assistant surgeon. Detached from the Navy Yard, Portsmouth, N. H., August 31, and ordered to command the Naval Hospital, Sitka, Alaska.

W. D. OWENS, assistant surgeon. Ordered to the Navy Yard, Portsmouth, N. H., and to additional duty on the "Southery," August 21.

E. C. TAYLOR, passed assistant surgeon. Detached from duty at the Navy Recruiting Station, Memphis, Tenn., and ordered home to wait orders.

W. J. ZALESKY, passed assistant surgeon. Ordered to the Navy Recruiting Station, Memphis, Tenn.

J. A. BIELLO, acting assistant surgeon. Ordered to the Naval Hospital, Philadelphia, Pa.

J. MCMAHON, pharmacist. Detached from duty at the Navy Yard, New York, N. Y., and ordered to the Naval Hospital, Norfolk, Va.

G. A. LUNG, surgeon. Detached from the "Kentucky" and ordered home to wait orders.

A. R. ALFRED, surgeon. Detached from duty at the Navy Recruiting Station, Pittsburg, Pa., and ordered to the "Wolverine."

A. G. GRUNWELL, surgeon. Detached from the "Wolverine" and ordered to the "Kentucky."

R. E. STOOPS, assistant surgeon. Ordered to the Navy Recruiting Station, Pittsburg, Pa.

K. C. MELHORN, acting assistant surgeon. Ordered to the Naval Hospital, Norfolk, Va.

R. S. BLAKEMAN, passed assistant surgeon. Discharged from treatment at the Naval Hospital, Norfolk, Va.

Address.

THE DIGNITY OF MEDICINE.*

BY IRA J. PROUTY, M.D., KEENE, N. H.

ANOTHER year has rolled around and been added to the life history of this society. Every passing year brings its changes which are noticeable at our annual gatherings. The familiar faces of those long in the ranks are missed one by one, while new countenances are seen, and new voices are heard in discussion and around our banquet board.

I am not unmindful of the honor you have conferred in asking me to preside over this venerable society, for it certainly is an honor to occupy the executive chair which has been so ably filled in the past by men who have achieved national and even international reputation. As I have looked back over the years of more than a century that mark the life of the New Hampshire Medical Society, and have considered the work accomplished by the thoughtful, earnest men who have spent their lives in riding through summer's heat and winter's blasts, over the hills and across the valleys of our rough yet productive state, on their mission to relieve suffering humanity, a feeling of regret has come to me that no more records of their lives and works have been left by them to help and encourage those of younger years.

Our society was the third state medical society to be incorporated. It has on its long list of members nearly all the names that have been prominent in our medical annals. It never has been in such a prosperous condition as at the present time; all of the ten component societies are doing good work in furthering the cause of scientific medicine. I have visited during the past year several of these local societies and have been impressed by the seemingly good fellowship that prevails and the interest taken in the work, as evidenced by the papers and discussions.

There is still missionary work for us to do, for there are two hundred or more physicians in the state who should be added to our already long list of over four hundred. The north county society is the banner one of the state, having the largest percentage of members in proportion to the whole number of physicians in Coos County.

In the early days of the New Hampshire Medical Society and before, the doctor and the minister were looked up to by every one in the community as standing on a higher plane in the possession of knowledge. The parson, with his long straight coat, high cut vest, and sanctimonious bearing, and the doctor, calm, dignified, and always carrying his mysterious leather bag, made the people of the New England village stand in awe of them. Hawthorne has given us in "The Scarlet Letter" a singularly truthful picture of the old-time doctor: "Made up of earnest, studious, thoughtful, quiet years, bestowed faithfully for the increase of knowledge, faithfully, too, for others, caring little for themselves, kind, just, true, and of constant, if not warm, affections."

To-day all this is changed. The people have become better educated, especially in matters pertaining to their own health (although there is still a chance for vast improvement in this direction), so that there is not the difference between the professional man and the community at large that there was at one time. The times have changed; conditions of practice have altered and are altering rapidly. When we look back into the days of old, we find that the ideals which inspired medical men then are our ideals to-day — ideals which are never old, yet always fresh and new.

The custom of opening our meetings with a general address is an appropriate one, for it affords an opportunity to discuss some topics which, although not strictly scientific, are of deep concern to each and every one of us. It is well at times to take a somewhat general survey of our profession, to study its tendencies, and get if possible a clearer vision of what should be its aims and ideals.

I ask your attention for a few moments to the subject of "The Dignity of Medicine."

I suppose no one in this audience will for a moment maintain that our profession holds the position to-day that it did when this society was young. The doctor is not looked upon as he was in the days when he entered the door with his saddlebags or when his sulky turned in at the gate. I desire to speak of the dignity of medicine as shown by its beneficent work, as a great social power in any community, and as spreading everywhere a wholesome influence. This is the particular dignity which appears to me to have declined in recent years and largely ceased to inspire the respect which is due to it. It rests with you and me to help to recover and reconstitute this dignity which in a measure has been lost. Whatever the explanation of the fact, for fact I believe it to be, there can be no doubt that any loss of appreciation of it or prestige is not due to decadence or inefficiency in the service of medicine itself, for the progress has been greater and more beneficial to humanity within the last few decades than during the previous two centuries. We notice on the part of the public either a spirit of indifference or a disposition to be over-critical. The proofs of this are lamentably notorious. The inadequate provisions made for measures of public health, for the prosecution of research, and for the sanitary services generally, all bear witness to a mistrust of the high aims of medicine and an indifference to the unselfish and ill-rewarded labors of our profession. The humane efforts fail to impress people of enlightenment any more than those of ordinary intelligence. Often our most prudent advice is treated with suspicion, and the advisers, although experts in their subjects, receive little serious attention. It might have been expected that with the progress of education there would be a corresponding interest in, and a growing appreciation of, the value of medical science in all communities. The discussion of medical subjects in the public press, instead of enlisting intelligent sympathy with the efforts

* President's address before the New Hampshire State Medical Society, Concord, N. H., May 16, 1907.

of our thinkers and workers, rather tends to place our patients in a wrong attitude towards their medical advisers, and induces a mood which sometimes seriously hampers the treatment of their ailments.

The relations between intelligent patients and physicians are not as satisfactory now as they used to be, and there is apt to be less confidence, if not at times an actual mistrust, on the part of patients which assuredly does not work out for their benefit. The fault must either lie at our own door and concern us individually or it must be a sign of the spirit of the age in which we are living. Thus even modern medicine with all its advantages, improvements, and enlarged resources stands before the public shorn apparently of much of its dignity and the appreciation it formerly enjoyed. A measure of dignity has been accorded to the Church, to the Law, and to Physic, and, as I have said, the latter, in more recent years, has not kept its place. I am almost sure that the former do not continue to hold their places as they once did; we are not, however, concerned with them; they can look out for themselves. It may be that there is a common cause for a decline in the public estimation of all these professions.

There are problems facing us to-day, the solution of which will raise or lower the dignity of our profession in the eyes of the general public.

In his individual capacity the doctor has not been found wanting. Wherever you may go in civilized lands, the physician will be found self-sacrificing, patient and charitable, upholding the honor and dignity of his noble calling. Collectively medical men do not have that influence which we might expect and without which great movements for the welfare of humanity cannot be carried on. A lack of unity has prevented a realization of our hopes, and if we gain and maintain the pre-eminent position to which we are entitled, we must unite for the common good. The present organization of the New Hampshire Medical Society and of the American Medical Association is but a beginning; we must further the interests of these bodies unselfishly, not for ourselves alone, but that we may better fulfill our sacred obligations to mankind.

The people must be educated to a point where they can understand the broad humanitarianism of modern medicine. Society fails to appreciate the priceless gifts to mankind made by preventive medicine and sanitary science. We have failed to secure the support of the mass of the people to much needed sanitary reforms because we have appealed to them as one individual to another without the weight of an authoritative organization.

This great association of medical men is a pregnant fact, and ought to be a powerful active factor in moulding public as well as professional opinion into such lines as should be conducive to public and professional interests. For while with us professional interests must naturally take the first place, it should never be forgotten that the main purpose of our existence as a profession is for the public advantage, and from such a point of view all our actions will be estimated by the world at large. The time has come for the public to be taken into our confidence; if we wish better results we must enlighten the people, for with them lies the final word.

The dignity of the profession, its social and political position, will be materially enhanced when the bonds of fellowship are drawn more closely than they have been in times gone by. When the bulk of the members of the profession take the view that in union there is strength, the means of achieving more complete and practical fusion of the various elements which are now too far sundered will be readily found. Our state society is a representative of the great idea of the unity of medical science. Here we meet on common ground and each member learns from the others and takes home with him to ponder over and use again what he has received from the common stock. Each one of us in our living should seek as far as possible not to forget that as the arteries permeate the whole body and are in uninterrupted communication with each other, so we can only maintain the integrity of medical science by keeping in view the intimate relations and mutual bearings of all the various departments which go to make up the unity of the sciences. The benefits accruing from a large society are many, not only to its members, but to the community at large. When there is the largest attendance and interest there is the greatest degree of unity and good fellowship which is essential to the dignity and usefulness of the profession.

The influence of this society, if judiciously used in establishing and maintaining relations of confidence between the public and our profession, is certain to increase, and when important subjects are under discussion it will be for you, remembering that you are citizens first and doctors afterwards, to formulate your views on the essential points at issue, and then to give a long push, a strong push, a push all together. If we would have our profession respected, we must respect it ourselves by never speaking of it lightly, slightingly, or in a depreciatory manner.

If the medical profession were composed of men of less charity and forbearance, an unappreciative public would be left to their own impotent endeavor to solve the problems of sanitation and protective medicine. Is it any wonder that there is a tendency on the part of some to abandon a thankless undertaking, for it really seems sometimes that in spite of our most loyal efforts it will always be "truth forever on the scaffold, wrong forever on the throne." Why the populace as a rule are less responsive to concerted action on our part than to individual effort can, in my mind, be explained only on the ground that when physicians band together for any accomplishment, even if for the health and sole welfare of the people, they are regarded as a trust, and the public generally is antagonistic to organization.

Compare this prejudice to medical organization with the general approval with which our

commercial bodies are regarded, and the result of such comparisons is almost disheartening. If a board of trade indorses certain legislative enactments for the protection of the financial interests of the community, the masses of the people have sufficient confidence in the integrity of such a board as wisely to rely on and be governed by its indorsement. The press will at once come to its aid and if need be a fund is created for the enterprise.

Let a medical organization, on the other hand, originate or indorse measures which have a vital bearing on the health of the same community and to whom will it look for support? The press is often subsidized by advertising charlatans, and the people, instead of according us their real support, are either indifferent to our efforts in their behalf, or are ready to rise in denunciation of our most honest purposes. The same confidence that is given us as individuals is denied us as an organization. It is our duty to create a healthy public sentiment, to educate the people to realize that we are striving to help them. Throughout our entire country I do not believe there is a law on a statute book passed at the instigation of the medical profession that is not productive of more benefit to the masses of the people than to the physicians themselves.

The unity which has long been desired by many for the profession at large is a unity without uniformity, a bond which allows of the freest individual development, while it serves only as a check to any outgrowths calculated to harm the commonwealth or to injure the neighbor. Such harm or injury may result from sins of omission as well as commission. It is important that in all we do or attempt to do, either as individuals or in combination, we should be studious to avoid, even in appearance, everything which might seem to the non-professional mind to savor of professional advantage, and we should never forget that we are professional men and not tradesmen. Not being wage-earners, we may guard ourselves against being misled into following the methods of those who at times are working for ends which appear selfish and from motives which sometimes seem unworthy.

The quarrels of doctors make a long chapter in the history of medicine. The larger quarrels are becoming less and less intense, and during the last century no new one of moment sprang up, while we can safely predict that in the present century, when science has thoroughly leavened the dough of homeopathy, the great breach of our day will be healed. In too many communities, both large and small, miserable factions prevail, while bickerings and jealousies mar the usefulness and dignity of the profession. Most of the quarrels among doctors are about the non-essentials, small trifles and annoyances — the pin pricks of practice — which perhaps would have tried the patience of Job himself.

The county society or local doctor's club is as professional cement. The meetings in a friendly, social way lead to a free and open discussion in a spirit that refuses to recognize differences of opinion. There is no room for envy, hatred, malice, or uncharitableness. By such gatherings there is brought about an attitude of mind which becomes habitually friendly, and a little of that old time courtesy and dignity which makes a man shrink from wounding another, especially a professional brother.

Much time has been spent uselessly in years gone by in formulating codes of ethics to govern physicians in their attitude towards each other. We should act as one gentleman naturally would to another. Rules and codes of ethics are only necessary for those who have not the instincts of gentlemen. To lay down rules for conduct in their relations with one another is puerile. It is sometimes required to tell boors how to imitate. Their effort at imitation is laudable but always transparent. As Herbert Spencer has well said, "Righteousness expresses of actions what straightness does of lines: and there can no more be two kinds of right action than there can be two kinds of straight lines." The rules for our guidance can all be summed up in that one great and golden rule laid down centuries ago, — "Whatsoever ye would that men should do to you, do ye even so to them."

We must not be surprised if we provoke misgivings on the part of the intelligent public as regards our level headedness and our honesty when we express dogmatically opinions regarding matters and life which are in plain contradiction to all experience and common sense. As in other professions we have in our ranks so-called "faddists" and it must be that they bring reproach upon many others besides themselves. It is not always easy to refute in public such opinions and conduct as I refer to, and most of us have sometimes to fall back on the wise dictum of Bishop Andrews, that "he who tolerates does not necessarily approve." We may be sure that anything approaching extortion or greed must seriously injure the respect which is due our profession.

The dignity of our profession is lowered when a physician's services can be bought at wholesale and peddled out at retail to further commercial ends, thus enabling canvassers and looters to catch members who are overpleased at being led to believe that they will be able to obtain good medical attendance upon the payment of a few dimes per month. It can only be regretted that there are among us such men who will be so misled as to sell themselves to such task-masters and to undertake professional work which they must know is not likely to be of much service to the public upon terms which they must feel cannot be remunerative to themselves. Some of you may say, "This is business." Weir Mitchell well says, "We are not business men; we belong to a profession and sell that which no man can weigh or measure." He further expresses the same thought: "How difficult it is for us to comprehend these men who are born and bred in a commercial atmosphere. They have set ideas and utter absence of tastes or pursuits outside of mere money making. They seem to have in life no other game."

Although, as has been said, we should not make our profession a trade, yet we certainly can, in a dignified way, stop being imposed upon by insurance companies, corporations, including hospitals and individuals, and under the so-called mantle of charity be defrauded out of our just dues. It is not the poor man with the family that asks the doctor to discount his bill, but very often the corporation or man with a good salary tries to impose upon us. We should willingly and at all times give our services to the truly worthy poor, but it must be left to us to decide who are worthy.

The greatest impediment to the dignity and progress of our art is now and ever has been the astonishing credulity of mankind in everything to which mysticism lends its false illumination. The glare of mysticism is too often mistaken for the light of science. In the words of a former president of this society, "Whatever is mysterious, or in the least partakes of the supernatural, forms no part of scientific medicine." "Knowledge comes, but wisdom lingers," and in matters medical the ordinary citizen of to-day has not one bit more sense than the old Romans, whom Lucian scourged for a credulity which made them fall easy victims to the quacks of the time, like the notorious Alexander.

Matthew Arnold defines charlatanism as the "confusing or obliterating the distinctions between excellent and inferior, sound and unsound or only half sound, true and untrue, or only half true." Napoleon one day, when somebody was spoken of in his presence as a charlatan, said: "Charlatan as much as you please, but where is there not charlatanism?" There certainly are charlatans and quacks outside of the profession, and must I say inside as well? If we of the household are not free from charlatanism and quackery, what of the people among whom we work? From the days of the sage of Endor, even the rulers have loved to dabble in it, while the public of all ages has ever revelled in its methods, — to-day as in the time of the Father of Medicine. Plato thus sketches the world-old trait: "And what a delightful life they lead! They are always doctoring and increasing and complicating their disorders and always fancying they will be cured by any nostrum which anybody advises them to try."

All departures from the accepted methods of healing, the breaking away from the conservatism and practices of the past, are not easy. We were schooled with the view that drugs were all-powerful, and consequently have allowed the dignity of our profession to become lowered by not investigating, until within the past few years, the use of remedies that are not drugs. The use of non-medical curative measures has been made prominent by such noisy pretense of skill in their use that reputable physicians have hesitated to take interest or to have confidence. The use of the various forms of electricity, hydrotherapy, massage and diet were practically under the ban, yet to-day we are beginning to see that they are among the most valuable remedies we possess. We should always bear in mind Sydenham's rule, "Whatever is useful is good."

A great feature of modern medicine is the return to psychical methods of treatment, the success of which depends upon the faith of the patient. There is a place in medicine for the practice of systematic mental therapeutics; and by the study of the subject and the employment of it in a dignified way, will result in its being taken out of the hands of "mental healers" and the like, just as the profession took surgery out of the hands of barbers and pretenders.

Faith is the great lever of life; without it, man can do nothing. Faith in us, faith in our drugs and methods, is the great stock in trade of the profession. Galen said: "Confidence and hope do more than physic, — he cures most in whom most are confident." That strange compound of charlatan and philosopher, Paracelsus, encourages his patients "to have good faith, a strong imagination, and they shall find the effects."

We often overlook or else are ignorant of our own faith cures, and are very sensitive about those performed outside the ranks. We must not expect to have a monopoly of this panacea, which is as free as the sun, and which may make every one in certain cases, as was the Lacedemonian of Homer's day, "a good physician out of Nature's grace." Faith in the gods or in the saints cures one, faith in little pills another, hypnotic suggestion a third, faith in a plain common doctor a fourth. The cures in the temples of Æsculapius, the miracles of the saints, the remarkable cures of those noble men, the Jesuit missionaries, the modern miracles at Lourdes and at St. Anne de Beaupré in Quebec, and the workings of the so-called Christian Scientists (no science and very little Christianity) are often genuine and must be taken into account in discussing the foundations of therapeutics. In the words of Osler, "The faith in which we work, the faith, indeed, which is available to-day in every-day life, has its limitations. It will not raise the dead, it will not cure cancer or pneumonia, or knit a bone; but in spite of these restrictions faith is a most precious commodity, without which we should find ourselves very badly off." The faith healing in these days, which goes under the euphonious name of Christian Science, is nothing more than mental suggestion. "The patient is told to be calm and is assured that all will be well: that he must try to aid the healer by believing that what is told him is true; the healer then quietly but firmly asserts and reiterates that there is no pain, no suffering, that it is disappearing, that relief will come, that he is getting well." A recent writer has pointed out that the growth of so-called Christian Science is that which underlies every popular fallacy. Oliver Wendell Holmes outlined very clearly the factors concerned, showing how easily abundant facts can be collected to prove anything whatsoever; how insufficient exalted wisdom, immaculate honesty, and vast general acquirements are to prevent an individual from having the most primitive ideas upon sub-

jects out of his line of thought; and finally demonstrating the boundless credulity and excitability of mankind upon subjects connected with medicine.

There is no profession whose members are less trammelled by precedent, tradition, or prejudice than ours. Every one of us is free to choose his own methods and remedies. No rulings or creeds limit the application of our logic; no councils instruct us where to go for facts. We can go contrary to all usages and introduce revolutionary methods, and the profession welcomes our work if only it is justified by results. In using remedies that are not drugs, and I may say those that are, we must not think one is a cure-all, using it for all the ills that flesh is heir to, for if we do we are resorting to the same quackishmethods of those from whose hands we have wrested these remedies.

The practice of medicine is an art, based on a science, working with science, in science, for science; it has not reached, perhaps never will, the dignity of a complex science with exact laws, like astronomy or engineering; but with the records made in the laboratories it is becoming more exact year by year. We must not rely entirely on the men behind the 'scope. An oft quoted saying of Bismarck's is, "Politics cannot be made in the laboratory: they have everywhere to do with human doings." In an analogous manner we may well say "that medical science cannot be exclusively made in the laboratory; it has always and everywhere to do with human beings." Dr. L. Emmet Holt has recently well said, "The men of the laboratory to-day dominate medical thought. They form sort of an oligarchy, to whose decrees those who study medicine at the bedside only must needs submit, often with a subconscious feeling of their own inferiority. I cannot myself resist the opinion that the man of the microscope and culture tube just now occupies a place of too great importance, at least in the minds of the medical student and younger practitioner."

Nothing has given a greater uplift to medical thought and practice, and especially to diagnosis, than the laboratory. Its aid is indispensable, but it has its own proper place. The work done at the bedside has, I am sure, been undervalued, and as a natural result the pendulum has begun its backward swing, and from both sides of the Atlantic come voices cautioning against the undue magnification of the laboratory at the expense of other aids to diagnosis. Cabot has well said, "After the student has learned to open his eyes and see, he must learn to shut them and think." The object of all medical science is to help and to heal, and the object of all medical, artistic and scientific thinking is therapeutic thinking. The peculiar problem that confronts us as physicians is not so much the disease as it is the diseased patient, and the significance of medicine is to be sought in this object, — to protect the highest possessions of human beings, life and health.

We must ever study at the bedside and not rely wholly on the findings in the laboratory. The knowledge acquired by both is the only practical knowledge. One is almost useless without the other. The alpha and omega of practical medicine is well expressed by Froude: "The knowledge which a man can use is the only real knowledge, the only knowledge which has life and growth in it, and converts itself into practical power. The rest hangs like dust about the brain or dries like rain drops off the stones."

Those of you who have recently entered the profession will find as those longer in the service have found that Bunyan expressed it only too truthfully when he said, "It happens to us, as it happeneth to wayfaring men: sometimes our way is clean, sometimes foul: sometimes up hill, sometimes down hill: we are seldom at a certainty. The wind is not always at our backs, nor is every one a friend that we meet on the way."

Let us strive as individuals and as a society for the honor and dignity of our profession, impressed by the importance of the problems which we as its ministers have to solve. In this we but follow out the aims and ideals of those who have gone before and blazed the way.

THE THREE LONG-CONTINUED FEVERS OF NEW ENGLAND.*

BY RICHARD C. CABOT, M.D., BOSTON.

Members of the New Hampshire Medical Society:

Mr. President: I wish first to express my gratitude to you for asking me to be present here, and to say that I am very sensible of that honor. I wish also to congratulate you upon the address to which you have just listened, to which I have listened with great pleasure and with most cordial agreement. I should like to refer particularly to the concluding portions in which your president has referred to the limitations of certain methods commonly classed as laboratory methods. I fully agree with him as to the limitations of those methods and as to the necessity of their being controlled always by bedside knowledge of the case.

I have chosen the subject which I am to put before you to-day because it has impressed itself upon me considerably in private work and in hospital practice, that there are in New England but three long, common, continued fevers, and also that there are some of the profession who do not realize this fact. I have spoken of my proposed address to a number of my colleagues in Boston, and most of them wondered what those three fevers would turn out to be. As long as that is so, and as long as the facts show that considerably over 90% of all long-continued fevers are due to one of three diseases it seems to be worth while to emphasize the point, to insist upon those three fevers and to speak of their diagnosis.

I must first define my terms. By "long fever" I mean a fever which lasts two weeks or more. That usage is arbitrary, but for the purposes

* Read before the New Hampshire State Medical Society, Concord, N. H., May 16, 1907.

of discussion is convenient. A continued fever is, of course, a fever which does not touch normal at any time during twenty-four hours, and by fever itself (I am going simply by temperature measurements) I mean any disease in which the temperature is continuously above 99° F. I have limited my title to fevers of New England because if one goes into the tropics one meets with a number of other fevers with which you and I do not deal. But as statistics (which I shall give you in a few moments) show, there are but three long, continued fevers of New England — *typhoid, tuberculosis, sepsis.*

My attention was first drawn to this fact by a series of discussions which I hold once a week with the students of Harvard Medical School, in which we take all the post-mortem examinations of the Massachusetts General Hospital and compare the findings with the clinical records. We found that in this particular series that 97% of all cases in which there was a fever of more than two weeks turned out to be typhoid, tuberculosis or sepsis. From those figures I decided to go over a much larger number of cases from private practice and from the records of the Massachusetts General Hospital, and found that the ampler statistics confirmed the earlier impressions. That these three fevers would together make up 90% of all the long fevers in any part of New England I have no doubt, but within *this 90%* the number of cases of tuberculosis, of sepsis or of typhoid would obviously vary a good deal according to the local conditions.

In a hospital like the Massachusetts General, for example, where we never take pulmonary tuberculosis except by mistake, we have, of course, a much smaller percentage of tuberculosis than in some general hospitals. In hospitals where the "surgical" cases greatly outnumber the "medical," the proportion of sepsis of one variety and another would be very much greater than in any hospital where "medical" cases are in the majority; but still, the general proposition with which I have started would be the same in any community, in any hospital, viz.: that 90% or more of the long fevers are due to one of these three diseases.

I will now give you the figures in detail. Out of 784 cases which I studied for the purpose of this paper at the Massachusetts General Hospital, we had 586 cases of typhoid. The next largest item was sepsis, with 70 cases, or 9%, and then tuberculosis with 54 cases or 7%. I must define a little more exactly what I mean by sepsis. I mean all the diseases due to the pus-forming bacteria which are prone to exert their influence in any part of the body. I include, of course, abscesses and wounds, deep or superficial; puerperal fevers, appendicitis, fevers originating in the gall bladder and the pelvis; also those hidden, dubious fevers associated with vegetations on the heart valves, commonly called ulcerative or malignant endocarditis. Those here grouped together are essentially the same in their etiology and their general prognosis, except where we can remove the cause.

Next to these three common fevers comes *meningitis;* although it is usually associated with a short fever or with one which often touches normal, it may produce a continued fever; and 27 of our cases of cerebrospinal meningitis were of this type.

Next to that group comes *influenza*, 10 cases. No doubt this number would have been much larger if I had not made the arbitrary limit of two weeks. Most cases have a shorter limit than two weeks. I have no doubt some of these diagnoses are wrong. The diagnosis of influenza is very difficult to make at present, and it is possible some of these 10 cases were mistakes.

Acute articular rheumatism, 10 cases. It may turn out to be true that this disease is due to a rather mild infection with pyogenic, pus-forming cocci; if so these cases would be classed with the other types of sepsis.

Then come 5 cases of *leucemia*, and 4 cases of *malignant abscess* with fever. After that, *cirrhosis* and *gonorrhea*, 2 cases each, and then 13 other diseases, one of each.

LONG FEVERS.

Typhoid,	586	
Tuberculosis,	54	
Sepsis,	70	
	—	710 or 90%
Meningitis,	27	
Influenza,	10	
Acute rheumatism,	9	
Leucemia,	5	
Cancer,	4	
Syphilis,	2	
Cirrhosis,	2	
Gonorrhea,	2	
"Scattering,"	13	74 or 10%
Total,	784	

Simply to know the facts shown in this table is of importance, because of the help it gives us in diagnosis by exclusion. If you have a continued fever, a long fever, you are pretty sure it must be one of three things. Then if you can exclude two of those three — as you often can — your diagnosis is made.

My next point is that the diagnosis of these fevers is *not only possible but important* because treatment makes so great a difference here. There are many diseases whose diagnosis is difficult but not especially important, because we cannot do much for them if we succeed in making the diagnosis. Your president touched on that point when he said that all scientific information, if it is to be important, must be scientific information that we can *use*. Many diagnoses of the rarer affections of the central nervous system, which take up nearly a third of the great books on diagnosis, do not seem to me very important, because we cannot do anything for these diseases, but the diagnosis of these three fevers is *important* because the treatment is important. And further than that, the diagnosis is usually *possible*, provided we think of it. The majority of mistakes in diagnosis which I have known in regard to these three fevers have been due to the fact that the infection which turned out to be the cause, was

not considered at all. If these causes are considered, they can usually be recognized.

A few words on the diagnosis of these fevers. I think it is first of all important to realize that there is no such thing as "simple continued" fever, "slow fever," or "low fever," or "bilous fever," or "gastric fever." Among the fevers which I have seen in consultation, a considerable number have been diagnosed as some one of these things. The fever, it is true, is often "slow," but is not properly diagnosed by recognizing that fact. It may be also "low," but that is not enough to characterize it. It often has important gastric symptoms, but those are not the cause of the fever.

We get down to business, then, by excluding once for all these exploded superstitions.

Another fact of importance is that in New England, aside from cases brought in from the tropics, there are no cases of malaria which run an obstinate, continued fever. All the malarial fevers in New England are intermittent fevers and yield readily to quinine. I have seen in consultation a considerable number of cases which had been diagnosed as malaria, despite the fact that they did not yield to large doses of quinine given over considerable periods of time. It seems to me that this argues an ignorance of the fact that all malarias originating in New England yield readily and quickly to quinine.

There are no long, continued fevers due to hysteria, neurasthenia or any other affection of the mind, and there are no such fevers due to constipation. These suppositions come up frequently in differential diagnoses, but I think they should be excluded. Disorders of the nervous system give rise to fever, but not to long, continued fever.

I will begin with the diagnosis of fevers due to tuberculosis. I have seen a number of mistakes and made a number of mistakes in this matter, by reason, first of all, of paying too much attention to the symptoms and not enough to the signs; too much attention to what the patient says and not enough to what we find on examination. Three times I have seen, in consultation, cases of pulmonary tuberculosis which were not recognized because the patient did not cough. It seems not to be realized by a considerable number of physicians that now and then a case of pulmonary tuberculosis may go on very far without any cough. I remember especially a case of diabetes in which the post-mortem showed that two-thirds of one lung was entirely solidified by tuberculosis; yet there was never any cough at all. These cases are very exceptional. I do not mean to say that the average patient with tuberculosis does not cough and cough early and often, but it does not seem necessary to say that we can have pulmonary tuberculosis easily recognizable under the stethoscope and on examination, but not giving rise to any cough. Such a case is sometimes diagnosed as typhoid, or "low," "continued" or "gastric" fever, when the patient ought to be treated and treated vigorously for tuberculosis if he is to be saved.

Sometime ago I saw in my office a young man who had recently coughed up blood. He had felt perfectly well before that and had no cough. I examined his chest rather superficially, because I didn't want to stir up more hemorrhage by deep breathing. I found nothing. I had no considerable doubt that he had tuberculosis of the lungs, yet found no signs in his lungs, nothing but the hemorrhage. But since experience shows that the vast majority of all hemorrhages from the lungs, in the absence of traumatism, are due to tuberculosis, I told him he should treat himself as if he had tuberculosis. He went home and two days after that I had a delighted message from his physician. He said: "You'll be glad to hear that Frank has developed typhoid fever; it is nothing worse." He was running, indeed, a continued high fever exactly like typhoid. I said, "Are you sure it is typhoid?" He said, "Oh, yes, no doubt about it." I heard nothing more about the case for a couple of weeks when the physician called me up: "Won't you come out and see that patient again?" I went out and found half of one lung solidified with tuberculosis. Well, nobody could have wanted more than that boy's physician did to do the right thing, but it was an awful mistake. There the boy was in the house; all the windows shut; getting the worst possible treatment. The boy himself was intelligent and as soon as he knew what the matter was he insisted on being kept out of doors; his temperature came down within a week, and I believe he is going to get well in spite of the tragic mistake of his physician.

These cases of tuberculosis of the lungs without cough are diagnosed in my experience as one of three things: either they are called malaria — and that they are called quite frequently because of chills — or they are called typhoid, or else the doctor refuses to call — doesn't call — them anything; just says, "He's got a fever."

Let us consider first the cases characterized by chills. It certainly should be recognized, and I think it generally is, that not only may we have chills in tuberculosis of the lungs without cough, but we may have *a chill every day at the same hour*. There are many practitioners who, when they have a case of chills every day at the same hour, will give quinine and assume the diagnosis of malaria, no matter what the physical signs are. In these cases the mistake is always to be avoided by examination of the blood. No one can have malaria and repeated chills without showing parasites in the peripheral blood. They are always to be found and the test is easy, quick and decisive.

I might, perhaps, say a word about the method of examination for tuberculosis, because, although it is a well-worn subject, we are learning more all the time about it. I learned something a short time ago during a visit to Dr. Trudeau at Saranac. You know the old procedure for bringing out crackling râles at an apex, by getting the patient to cough and then breathe just after it. A patient came to me the other day to be examined for lung trouble. After I had made her cough and breathe in this way she said: "I can always

tell whether a man who examines my lungs knows how to do it; if he doesn't make me cough and then breathe, I know he doesn't know his business." I thought I would pass that on to you for a hint to be remembered. Luckily, I happened to know that point and so didn't fall under her disapproval.

Dr. Trudeau and his assistants not only make the patient breathe hard and cough, but prescribe first a long inspiration, then full expiration, and a cough at the end of expiration. That they say will stir up râles and make them audible when nothing else will do it. That was a procedure I hadn't known and therefore I pass it on to you. The patient should always be examined in a quiet room; that is one of the necessities of the case and it is not always obtained. One can hear in a quiet room sounds which one misses otherwise. It is a good idea to wet the bowl of the stethoscope with water so it can't possibly slip upon the skin. Vaseline and grease are often used, but water does just as well and is much cleaner.

I pass to typhoid and its diagnosis. The history of the Spanish War of 1898 brought out very forcibly the fact that the practitioners who served then as contract physicians did not know typhoid when they saw it. When looking into that fact and the reasons for it, the commission appointed for the purpose seemed to believe that the reason these cases were not recognized was the lack of local symptoms. "These soldiers," the contract physicians argued, "have no diarrhea; they have no distention; they have no pain in the abdomen; how can they have typhoid? They feel pretty well and they are walking about." So the case was called "simple continued fever" and "gastric fever" and so on. I think it still needs to be said that typhoid in the majority of cases presents the picture of a patient who has fever *and nothing to show for it;* a fever and nothing local to account for it. I have been struck many times, when I was going over the abdomen of a typhoid patient, by hearing him say, "What are you feeling around there for? I am sick in my head and chest; I am not sick in my belly." The patient does not usually complain of his belly. He may have distention, but if the case is mild he usually does not, and in the great majority of cases he does not have diarrhea. Large statistics show that 75% of the cases of typhoid have regular bowels or constipation. This is natural, because it has become more and more obvious that typhoid is not a disease of the intestines at all, any more than diphtheria is a disease of the throat. It is a disease which has lesions in the intestines, but a disease in which bacteria are circulating through every organ in the body. It seems to me that the cultivation of the bacteria from the blood ought to become, more than it has, a routine method of diagnosis, although, of course, it needs a laboratory to have it properly carried out. Every considerable town ought to have such a laboratory where men can send to get the cultures and have their cases studied out from the bacteriological point of view.

Typhoid, then, being a general disease and not a local disease, a general bacterial infection, we ought not to expect local symptoms, ought not to think of it as a disease of the intestines. On the other hand, it seems to me that the importance of *negative evidence* is very great. Typhoid fever is oftenest the fever in which you do not find anything on physical examination. You may find enlarged spleen; you may find rose spots, but in many cases you don't find either. *You have a fever and nothing to show for it.* If you have the time and ability to make the blood tests, you do find something sooner or later in 99% of all cases, but still it is one of the fevers that show nothing on ordinary physical examination. We are realizing more and more, I think, that people may not only have typhoid fever and walk about with it, but may have typhoid and *no symptoms whatsoever*. The cultures from the gall bladder, taken at operations for gallstones, show typhoid bacilli so frequently in patients who never knew they had any fever, that I cannot help believing that people often have typhoid and do not know it. It has turned out that these poeple that have typhoid and do not know it may carry around bacilli in their gall bladders, which are emptied from the gall bladder into the intestines, and hence that the feces constantly contain bacilli, and are a menace to the community. I have no doubt that in some cases which cannot be traced to water or milk, such a perpetual "carrier of typhoid" is at the root of the whole trouble.[1]

Now, lastly, sepsis. Defined as I have defined it, sepsis is due to pyogenic cocci which may exert an effect on any part of the body. The great majority of such cases are diagnosed rightly. The sepsis has an obvious focus somewhere. The occasional mistakes of diagnosis are most apt to concern the liver. Abscess of the liver, whatever its source, very often gives rise to no local symptoms whatsoever; no pain, no tenderness; nothing but a fever. I remember two such cases taken for typhoid because of the apparently negative physical examination, cases which only at the end of a number of weeks showed their true character by the burrowing of pus to the surface. In the depths of the liver there are no nerves, therefore no sensation, no pain until the abscess burrows to the surface where the nerves are, and there gives rise to tenderness and pain.

I suppose we have all seen puzzling symptoms in cases following appendicitis in which the temperature had gone down to normal; then later the patient began to run a little fever, again with nothing to show for it on physical examination; perhaps a little bit of dullness in the right back, a little bit of what you might think was thickened pleura, but not enough to account for the fever. Those cases of unexplained fever after operations for appendicitis turn out generally to be abscess of the liver. The affections of the gall bladder are complicated in the same way by liver abscess, although the diagnosis is usually more obvious. Frequent in persons who have been in the tropics are the liver infections resulting from dysentery. Then there are the subphrenic abscesses burrow-

[1] See Jour. of the Am. Med. Asso., June 10, 1907.

ing under the diaphragm and originating most often in a perforating gastric ulcer. Those sometimes give no local symptoms. Temperature chills and leucocytosis may show us that there is pus somewhere, but give no idea where it is. Then there are the recognized cases of empyema following pneumonia. It has been well said that the vast majority of cases of unresolved pneumonia are really empyema.[2] I believe the number of cases of unresolved pneumonia is very small. I have seen them in post-mortem, but the vast majority of pneumonia cases that last more than ten days are empyema unrecognized. In these cases exploratory puncture ought to set us right, but I believe the diagnosis of empyema should never be excluded unless the chest has been opened, a rib removed and a thorough exploration made.

The continued fevers connected with the heart are often overlooked because they do not often give rise to any marked cardiac symptoms. The patient does not complain of his heart; he has heart murmurs and high leucocyte count, but he runs a simple fever often exactly like a typhoid and does not seem very sick. I think the term "malignant endocarditis" is responsible for wrong diagnosis in many cases. Endocarditis is pretty bad anyway, and if it is "malignant endocarditis" we think the patient must be very sick, yet many of them are not very sick. They are bright, feel well, eat well, sleep well, and you can't help believing that they must have some less serious disease with some less bad-sounding name; yet they will go on for weeks with nothing but a simple fever and finally die of exhaustion. In the diagnosis of these cases we depend on the presence of murmurs in the heart, the shifting of those murmurs from time to time, and the continuous presence of a high leucocyte count, which would not be present in typhoid, nor in uncomplicated tuberculosis.

In conclusion, then, summing up what I have said, I think it is important to realize the fact implied in my title, that there are but three common, long, continued fevers of this vicinity. Second, that these fevers, though often confused with each other and so unrecognized, can be recognized in the vast majority of cases provided we think of them at all and look for them carefully by the ordinary methods of physical diagnosis.

DISCUSSION.

Discussion of Dr. R. C. Cabot's paper opened by Dr. William T. Smith, Hanover.

We are all of us under obligation to Dr. Cabot for his very clear work on diagnosis, and he has added very much to that to-day, to my mind, by this discussion.

It is very gratifying to me to hear what he has said about fevers, for I have always felt that this was about as mystifying a portion of the ground that we are on as any. I think we have all found in our own experience many cases which we are unable to diagnose, and we have found many cases — all of us, undoubtedly — of wrong diagnosis between these different fevers, and where the names that he has suggested have been applied without any rational ground. I wish that what he has told us to-day might be incorporated in our textbooks. The trouble, of course, with the textbooks is that they undertake to cover the whole ground for all parts of the country, and the medical student in studying about fevers takes them all in as about on the same plane, and when he comes to apply what he has learned he is very apt to apply a name for a disease which is found only in the tropics to a condition which he finds in New England. It seems to me that what Dr. Cabot said about the limited number of continued fevers is perfectly true, and that we ought to recognize that fact, that it ought to be impressed on the minds of young men beginning practice.

Another thing that this paper makes me wish is that we might have blood examinations done free of charge by the state laboratory. Now our state laboratory is entirely capable of doing that work and does that work constantly, but it has to be paid for, and the result of that is that in many cases where the patient is poor and is not able to pay the fee, the blood examination is neglected where it ought to be made, where it would clear up without any further trouble the diagnosis. That is the practical point which I shall carry in my mind until we secure for ourselves at public expense the opportunity of having the blood of our patients examined at any time.

THE ORGANIZATION OF TUBERCULOSIS CLASSES.*

BY JOSEPH H. PRATT, M.D., BOSTON.

The Emmanuel Church Tuberculosis Class was organized July 1, 1905. Since that time fifty-four consumptives have been members of the class. Seventeen have already recovered and returned to work. The disease has been arrested in 75% of the incipient and moderately advanced cases. The first three members who joined the class within a few weeks of its formation have been at work over a year. Although they had advanced tuberculosis the disease became entirely arrested, and they were restored to their full working capacity.

A description of the class method of treating pulmonary tuberculosis will appear in the next volume of the Transactions of the National Association for the Study and Prevention of Tuberculosis.

Three additional tuberculosis classes have been formed in Boston. The Suburban Tuberculosis Class was started by Dr. John B. Hawes in January, 1906. It was designed for patients who lived too far from the city to be visited by the nurse of the Emmanuel Church Class. The Arlington Street Church Tuberculosis Class is under the charge of Dr. N. K. Wood. It has been in existence over a year. Recently a class intended for principally Jewish patients was started by Dr. H. Linenthal and Dr. L. Mendelsohn of the Mt. Sinai Dispensary. A friendly visitor was selected who could speak Yiddish. The Cambridge Tuberculosis Class was organized by the Cambridge Anti-Tuberculosis Society in 1906. About six months ago classes were started in New York, Philadelphia and Baltimore, and more recently in Lynn and Brockton. Steps have been taken to form classes in Washington, Pittsburg, Troy and Los Angeles.

* Read before The Massachusetts Medical Society, June 11, 1907.

There are several advantages of the class method of home treatment over sanatorium treatment. It is more economical. There is no expensive plant to be erected and maintained. The money appropriated can be at once utilized for the care of consumptives. If the patient regains his health in his own climate and in his own home it is easier for him to keep up the hygienic life after he has returned to work. With a class of small size the physician and nurse can give more attention to the individual patients than is possible in most sanatoria. Early cases in other members of the family are more readily detected. The educational effect on the patient's friends and neighbors is greater.

The disadvantages are equally apparent. It is easier to secure the necessary control so essential to successful treatment in a sanatorium where the patients are always under the eye of the directing physician and the nurse. Better food and better care can usually be given a poor patient in a well managed sanatorium than in his own home.

In organizing a class the first task is to secure its adequate financial support. The Rev. Dr. Worcester of Emmanuel Church has raised about $1,000.00 a year for our class. This has been obtained by Sunday collections and by individual gifts. The first grant of $500.00 was obtained from a fund known as the Parish purse which is placed at the disposal of the rector. Facilities for leading the out-of-door life, such as tents, reclining chairs and blankets have been provided and medical care and the services of a paid nurse furnished.

We have not attempted to treat homeless and destitute consumptives. Some of our members have been aided by small allowances, and in a few instances board and room rent have been paid. It has been a constant aim to place the responsibility of the support of our members on their own families. Our work could have been made more efficient, not so much by increasing our membership as by increasing the financial aid to some of our poorer members during the period after recovery while suitable work was being sought. One of our class to whom we made an allowance of $1.00 a week and who also received $2.00 weekly for a short time from a Jewish charity was so pressed for money that he was forced to pawn his watch and his wife's wedding ring. Knowing the small amount of money in our treasury he took this step rather than apply to us for more aid. A graduate with no resources and a child dependent upon her was forced to accept a situation as waitress in a restaurant where the hours of work were from five in the morning until ten in the evening.

Dr. F. T. Fulton secured the necessary funds for starting the Providence Class from the Social Service Club of the Central Congregational Church of that city. He arranged for a representative of the Emmanuel Church Tuberculosis Class to give an account of the class method and the results obtained at the church. A series of lantern slides was shown and charts and records kept by the members of the class were exhibited. After this demonstration the club voted to appropriate $500.00 for the work.

A Boston woman, not connected with Emmanuel Church, became interested in the movement and arranged a small home meeting to which four of her friends were invited. After the method of work had been explained these five ladies subscribed $500.00 for the formation of a new class, the success of which in the hands of Dr. N. K. Wood was such that at the end of six months the Arlington Street Church was willing to assume the maintenance of the class. Dr. J. B. Hawes secured both money and volunteer visitors for the Suburban Tuberculosis Class by publishing an appeal in the Boston *Transcript*. Ex-Governor Douglas announced the day after the formation of the Brockton Tuberculosis Class that he would finance the enterprise and gave at the same time $1,000.00. The establishment of the Mt. Sinai Tuberculosis Class was made possible by Mr. N. L. Amster's gift of $500.00 for this purpose.

A young woman in New York raised among her friends sufficient money to start the first tuberculosis class in that city. It has already done a remarkable work. The director, Dr. W. L. Niles, has demonstrated that tuberculosis can be successfully treated by the class method under unfavorable conditions in the crowded sections of New York City. Dr. David Riesman's class in Philadelphia has been supported by one gentleman whom he interested in the movement. The expenses of the Baltimore class have been largely borne by Dr. Dencker, who in addition has given his entire time to the work. In Lynn circulars calling attention to the class method were sent out and by this means sufficient money was obtained to start a class. In Troy a society for the home treatment of tuberculosis was established under the patronage of influential men. Many people became interested, so that $1,200.00 have already been secured by five and ten dollar subscriptions. A copy of the circular issued by this organization will be found at the end of this paper.

These facts are presented to point out the various ways in which classes may be supported.

The co-operation of all the local charitable, religious and fraternal organizations should be secured. Although in a large city such as Boston a class may be maintained by a single church, it will be the better plan in most instances to have the work started under the auspices of some organization that can look for support to the entire community.

Failure will certainly result unless the services of a physician and friendly visitor are secured who are familiar with every detail of the modern treatment of consumption. Our work would have been impossible if we had not had from the beginning the services of a paid friendly visitor. She was expected to devote half of each day to the work. As a matter of fact our friendly visitor, Mrs. Oreon, has frequently insisted on working many additional hours. Our success has been chiefly due to her tireless devotion. I

recently learned that she called daily for two weeks on one patient before she could induce him to sleep out of doors. He was an ignorant man and his friends and relatives warned him that death would surely follow if he made the attempt, as it was mid-winter. He has been sleeping in the fresh air for over a year and has not only gained the sixty pounds he had lost but the disease has been arrested and he has returned to work.

It is not necessary that the friendly visitor should be a trained nurse. Constitutional energy, tact and sympathy are the essentials. There have been several notable instances in which the work of the friendly visitor has been most successfully carried out by young women who have had no hospital training. Volunteer visitors can be of great assistance. We have had two volunteers who, working with the friendly visitor, have rendered efficient service in the solution of the social and financial problems. The social aspects need to be studied. They are quite distinct from the medical side. Students of sociology should join heartily with medical men in this work. The medical direction should be in the hands of one physician. He should be paid a salary sufficient to enable him to devote a fair portion of his time to the class and make a special study of the disease he is called upon to treat. A few weeks spent at Saranac or at the Phipps Institute in Philadelphia would be invaluable. Those in charge of the Boston classes will be glad to give instruction in the class method. It has been found that the tuberculosis classes have furnished an excellent opportunity for the physicians connected with them to acquire a good clinical knowledge of pulmonary tuberculosis.

Much depends on the selection of cases. The fact that all of our 9 incipient cases have recovered while 7 of the 10 far advanced cases have died indicates the value of early diagnosis and prompt treatment. Treatment is never begun too early; it is often begun too late. For the reason that the disease may be so insidious in its development and because recovery is not only more sure but more rapid when the patient is at rest, we have insisted that all of our patients should cease their work and devote themselves entirely to the task of getting well.

The present wave of optimism in regard to the treatment of consumption has its dangers. Many physicians make the fatal mistake of minimizing the seriousness of the disease in its early stages to both themselves and their patients. I am often asked by physicians to treat in our tuberculosis class consumptives "who are not sick enough to give up their work" or "who cannot afford to stop working." I am glad of this opportunity of pointing out to the members of The Massachusetts Medical Society their great responsibility in this matter. To let a man continue at work after the diagnosis of active pulmonary tuberculosis has been made is as foolish as it would be to let a fire burn unchecked until it became serious before calling the fire department. Doctors and social workers frequently speak of their inability to persuade consumptives to leave their work and take the rest treatment. This failure is usually due in the first place to the consumptive's ignorance of his true condition and, secondly, to his lack of financial resources. We have overcome these obstacles by telling him the truth and by promising that if he will join the class, keep absolutely quiet, sleep out of doors and follow our guidance in all things we will see that the ways and means are furnished.

When a suspected case is submitted to us a definite diagnosis is always made before treatment is instituted. If tubercle bacilli cannot be demonstrated in the sputum, the tuberculin test is tried. I have seen no harm result from tuberculin in the hundred or more cases in which I have used it. The initial dose I employed is $\frac{1}{10}$ of a mgm. If there is no reaction a second injection of 1 mgm. is given, and if necessary a third test with 10 mgm. is made. The details of preparing the dilutions will be found in the recent paper of my associates, Dr. Hawes and Dr. Floyd.[1] After the diagnosis has been made the patient is told that he has consumption, and if unwilling to heed our advice the seriousness of the disease is impressed upon him. In the old days, I have frequently overheard a conversation somewhat as follows between the hospital externe and a patient in whose sputum tubercle bacilli had just been discovered. "We find a little trouble in your lungs," began the doctor speaking rather hesitatingly, "I don't suppose you could give up your work for a few weeks and go to the Rutland Sanatorium, could you?" "No," said the patient, "I have a family to support and no money." "That is too had," said the doctor, "it would be better if you could stop work and go to Rutland, but as you cannot do that be sure and stay out of doors all you can, eat plenty of food, take this medicine for your cough and come back and see me in two weeks."

I never saw cures produced by this method, and my experience accords with that of my colleagues.

Since the tuberculosis class was established I cannot recall a single instance in which we have failed to induce a man of fair intelligence and good habits to stop work and to take the treatment. If a man tells me he has a wife and children dependent upon his weekly earnings and no money on hand I advise him to explain the situation to his relatives. Often there is a brother-in-law who is earning fair wages. I try to impress the following facts upon the sick man: the disease has its clutches upon him. Soon his strength will begin to fail and within a few months in all probability he will be too ill and weak to work. Then he will tax the resources of his family to the utmost. Often some one who might be earning money must remain at home to care for him. In addition to the expenses of his illness there is the increased financial burden attending death and burial. After the breadwinner is dead, provision must be made for the wife and children, not for months but for years. It is cheaper for the consumptive to get

[1] Bost. Med. and Surg. Jour., 1907, clvi, p. 694.

well than to die. This plain speaking may seem brutal, but it is often the means of saving life. It is a line of argument that rarely fails with the relatives. If they refuse to loan money, we have been able to secure from other sources the necessary funds to enable the patient to take the treatment.

In Oxford, Providence and Brockton several large manufacturers have provided free treatment in sanatoria and at home for consumptives in their employ. Dr. F. T. Fulton, of Providence, has found that those men who began treatment before constitutional symptoms had developed were able to return to work within a few months. Among these there has been thus far no recurrence of the disease.

Our greatest need in the Emmanuel Church Tuberculosis Class is provision for the exceptional cases who need prolonged financial aid, and for the after-care of our graduates. Many difficulties, financial and sociological, are presenting themselves. The medical problems have been largely solved. Much could be accomplished by giving a small allowance to the individuals in whom the disease has been arrested while they are seeking suitable employment. In Bardswell's valuable monograph on the Consumptive Working Man will be found the report of an after-care committee, as it is called, which was organized by the Kelling Sanatorium at Holt, Norfolk. This committee sent a printed leaflet to employers of labor, a copy of which will be found appended to this paper. There is urgent need that similar committees be formed in this country. In England employment was furnished chiefly by people with gardens and by farmers. Light work indoors is better for a consumptive with arrested disease than heavy work out of doors. If obliged to spend the day in-doors the individual with arrested disease should not fail to sleep in the open air.

The establishment of a loan fund for the benefit of individuals of good character in the curable stage of the disease would be of great economic and philanthropic value. The administration of such a fund might be quite independent from that of the tuberculosis class. In some cases the issue between life and death depends upon whether or not there is an available fund of a few dollars a week. Our patients are of entirely different type from those familiar to charity workers. In the majority of cases the disease had been the indirect result of over-work. They are thrifty and are able to live quite comfortably on little money. The fact that they carry out the class treatment faithfully for weeks and months indicates that they have perseverance. If such a fund is established loans should be made only after the needs of a case have been most carefully investigated. As only a limited number of cases can be helped at first preference should be given to those who can be most quickly and surely returned to the ranks of breadwinners. Patients who have used alcohol to excess should be viewed with suspicion. An intemperate man under our care who made speedy and marked improvement went on a debauch with the first money he earned after returning to work. Experience with young married women is also disappointing, for the reason that pregnancy and child-birth are so apt to be associated with a lighting-up of the disease.

If there are children in the family and the resources are scanty it is well to find temporary homes for them in the country, especially if the mother is tuberculous. In this work we have been greatly aided by the Children's Mission. Not only does the removal of children lessen the difficulties of caring for the family, but it often saves the children from becoming victims of the disease. We found unsuspected cases of tuberculosis among the children in no less than twenty per cent of the families represented in the class at the present time.

Attention should be called to the establishment in New York of a special employment bureau for the handicapped.[2]

If after-care committees be formed in connection with our tuberculosis classes it is probable they would proceed on somewhat similar lines. An effort should be made to interest the employers of labor in this work. The positions of watchmen or care-takers should be specially sought for our graduates. Honest, sober and reliable men could be furnished.

Most of our graduates have been able to return to their former employment, and yet maintain their health. If arrest is secured in advanced cases only light work under favorable conditions should be attempted. It is even more difficult to secure suitable work for women than for men.

A specific instance of the difficulties that confront us may be given. In November, 1906, a type-setter entered the class with incipient phthisis. He owned a little property in England, and although he earned fair wages had saved no money. His wife was a nervous invalid, unable to take boarders, and there were two children to be cared for. We turned to Mr. A. M. Wilson, the efficient secretary of the Boston Society for the Relief and Control of Tuberculosis, and he was able to obtain a weekly loan of $10.00 for a period of about two months. The property in England was not regarded as good security, and he was unable to dispose of it. After this relief failed a lady in the Emmanuel Parish loaned the same amount weekly for four months longer. The disease in the lungs became completely arrested. About six weeks ago, just as he was on the point of returning to work, symptoms of tuberculosis of the spine developed. For nearly a month he received free treatment in the wards and convalescent home of the Massachusetts General Hospital. Last week we were told by the orthopedic surgeon to whom we referred the case that an apparatus to hold the spine immobile must be worn for three months more. The outlook for complete recovery is good. He feels well and strong, but so long as he is obliged to wear the plaster cast he will be unable to do his work as a "job compositor." The printing firm for whom he worked has held

[2] See the interesting paper by T. C. Janeway and C. C. Carstens in *Charities*, Feb. 3, 1906.

a place for him. What shall be done in this case? There is the rent to be paid and the family to be fed. At the last meeting of the class the friendly visitor reported that there was no food in the house and he had to borrow a nickel for his car fare from a neighbor. I am glad to report that he received this week $10.00 from the class fund. Only temporary aid can be furnished from this source. Inasmuch as the total amount of money at our disposal is not over $20.00 a week it can readily be seen that we cannot pay out $10.00 weekly to one individual for any length of time. What better memorial for a relative or friend could there be than the establishment of a loan fund for cases such as this?

To show what can be done with a small amount of money the case of a young seamstress may be cited. She consulted a physician in the spring of 1906 on account of a cough. He found tubercle bacilli in her sputum and referred her to our class. She had only $50.00, and her parents who lived in Nova Scotia were too poor to help her. She was boarding with a friend who charged her only $2.50 a week. We gave her this amount weekly for four months and loaned her a tent and reclining chair. She enjoyed the privileges of the Parker Hill Day Sanatorium where lunches and a good dinner were furnished free. She entirely recovered and returned to her home in Nova Scotia for the winter. She writes that she has been perfectly well since graduating from the class and expects to return to work soon. Who can doubt that the loan of $40.00 saved her life?

The social and economic aspects of this movement are assuming increasing importance. Is it not possible that in the practical work of the tuberculosis crusade the sociological and medical departments of our universities may combine? The churches with their organized forces might furnish great aid if they were awake to their opportunity.

Although it has been demonstrated that the class method furnishes an economical and efficient means of treating tuberculosis in the homes of the poor, three important points should be borne in mind if the tuberculosis classes are to be successful. First, they should be directed by physicians familiar with the details of the modern treatment, and the right women should be selected for the position of friendly visitor. Second, there should be adequate funds for the support of the class. Third, every physician in the community should learn to recognize the disease in its early stages and to refer the cases for treatment without delay.

Appendix.

Copy of the circular issued by the after-care committee of the Kelling Sanatorium.

To Employers of Labor and Others Interested in the Working Class Consumptive:

It is felt that it should be more generally recognized that, in dealing with consumption, sanatorium treatment is only the first step.

Of suitable cases, treated at a sufficiently early stage, a large proportion are discharged fit for work, but if the good gained at the sanatorium is to be maintained it is essential that the patient should, on leaving, be able to go to suitable employment in suitable surroundings.

The Committee of the Kelling Open-Air Sanatorium, feeling the vital importance of this side of the work, have appointed a special sub-committee called the After-Care Committee, who consider the future of each of the sanatorium patients, and where necessary endeavour to obtain suitable work for him when he leaves such employment and surroundings.

Work is provided for a certain number at the sanatorium itself, but as it is impossible to provide in this way for more than a very small fraction of those discharged, the committee now venture to appeal to employers of labour to assist them.

They can help, it is suggested, in two ways:

1. By being willing now and then to find temporary light work for a man.

2. By occasionally giving one of our men the chance of a suitable permanent position.

In the first case the idea would be to enable the man for a short time to earn a bare living wage in suitable surroundings while he looked about for permanent work, and, in the second, to provide him, at no doubt a moderate wage, with suitable permanent employment.

Our men are almost all skilled in some trade, and we would obtain in every case a character from the previous employer.

It would be clearly understood that no responsibility whatever as to the man's health should be undertaken by the new employer; if a man so employed should break down, the committee would like to be informed, and would do all they could to secure him further treatment.

The employment may be either out of doors or in pure air in-doors. It should not involve any great physical effort, nor should it require to be done against time or high pressure.

The following list contains a few of the employments suggested:

Light work about a farm or garden.
Driving.
Care-taking.
Agency work as, for instance, insurance agency, rent collecting, or some form of travelling, etc.
Clerical work if in good conditions.
Estate work, such as light carpentering, looking after an engine, etc.
Motor car driving.
Check taking.
Door keeping, and many others.

The risk of infection has been mentioned as an objection, but there is no doubt that it has been greatly exaggerated and, in any case, it is certain that a man who has been treated at a sanatorium, whose symptoms have disappeared and who has been taught the precautions, is not only unlikely to be a source of infection, but is actually a missionary of health to all with whom he comes in contact.

The preferential consideration given to subscribers with respect to the admission of patients into the sanatorium will be given to any employers who will consent to give, instead of a subscription in money, this invaluable practical aid.

May we write to you when we want employment or a man? Please reply to ——, the Hon. Sec., Kelling Open-Air Sanatorium, Holt, Norfolk.

Copy of the appeal for the Society for the Home Treatment of Consumption in Troy.

"We must care for the consumptive in the right place, in the right way, and at the right time until he is cured; instead of, as now, in the wrong place, in the

wrong way, and at the wrong time until he is dead." — PRYOR.

There has been, during the last few years, a great revival of interest among both physicians and business men in the question of consumption. Every one is coming to realize that this plague is the most dangerous of any kind that we have to contend with.

It kills, every year, more people than any other disease. Last year there were 240 deaths from consumption in Troy, an average of 20 each month. The great majority of the deaths were among the poor between the ages of 20 to 40 years, the time of life when men and women are most essential to the support of their families and of their children. They cannot go away or receive the benefits of treatment in a sanatorium, therefore they must be cared for at home.

In many cities of the United States measures have been taken to fight this disease and the results have been remarkable. We are going to fight consumption in Troy and we ask for your interest and assistance.

A class is to be formed of consumptives who cannot afford to leave home to go to a sanatorium or to pay for continuous medical care. The society has secured the voluntary services of Dr. H. W. Carey as physician-in-charge, and Dr. H. C. Gordinier and Dr. J. B. Harvie as consultants.

The class will be under the care of the physician and a nurse who will instruct the patients in the three essentials for recovery — *Rest, Living Out of Doors and Proper Food.*

The class meets once each week for examination by the physician, and each member is visited at the home by the nurse, who will see that the instructions are properly carried out. This is the method used so successfully in Boston, Providence and New York, where, in most instances, the progress of the disease has been arrested, in many instances cured.

The cost of maintaining the class is $50.00 a patient a year, the expenditure being limited strictly to the purchase of tents, cot-beds and reclining chairs to enable the patient to live comfortably out of doors and to pay for the services of the nurse. In order to meet the expenses of carrying on the work for a year we must have $1,000.00 in hand and we ask your aid by a contribution of $10.00.

DISCUSSION.

DR. JOHN B. HAWES, of Boston: I have been associated with Dr. Pratt right from the start, and from the very beginning I was tremendously impressed with what this class method can accomplish. There is one thing which he has not mentioned, and which I think is one of the principal factors in successfully handling these cases, and that is, the personal element. Every one of these patients who have come here to-day is a personal friend of mine. They are being taught how to help themselves. As Dr. Pratt's class increased the need of another class was apparent, and there was another started at the Massachusetts General Hospital under my charge, and this was called " the suburban class," of which there are now three. The patients sleep out of doors wherever possible, and come to the hospital for the class work once a week when they are able, where we talk over the details of the past week. The first patient shown here by Dr. Pratt had been under my care at the hospital for six weeks, and nothing seemed to be accomplished under the old out-patient system until Dr. Pratt commenced this system of personal supervision of the patients in their homes, and to the hard, individual, personal work which he has put into it, I think the credit is largely due.

DR. I. J. CLARK, of Haverhill: A year ago there was a committee appointed in Haverhill to look into this matter, and to further the treatment as much as possible. This committee included members from Lawrence, Newburyport and our own town. I am very glad to report that we have organized a society in Haverhill, and solicited funds from our people. We have officered it with about all the doctors and clergymen, and I have patterned it as far as possible after Dr. Pratt's method. It does not seem practicable to have a class at present, but I have suggested it to the supervisor. I intend to work with him in carrying out the details. We are also to have the state exhibit. It seems to me a movement which every town of any size should take up. It is surprising to see how much interest in this is shown by the public. I do not think the matter will lack for means. I am very much interested in this matter, and will say that we find it very difficult to carry out the rest treatment. I had a patient recently who by careful supervision and treatment had become much better with no fever, but he insisted on going camping out and fishing trips, and he had a relapse. He did very well, however, under the treatment while he remained quiet.

DR. DAVID TOWNSEND, of Brookline: There is one phase of the work which has not been mentioned, the " Day Camp." The Boston Association for the Relief and Control of Tuberculosis has operated such a camp the past two summers on Parker Hill in Roxbury through the courtesy of the Robert Brigham trustees. This summer the camp has been established on the estate bought for the proposed Municipal Consumptive Hospital through the courtesy of the Municipal Hospital trustees. The camp is modeled after those in Germany, particularly those in Berlin. The patients come for the day only, they arrive early in the morning and go home late in the afternoon. They are given two lunches, one at ten, the other at four o'clock, and a dinner in the middle of the day. Each patient is examined once a month, and weighed once a week; his pulse and temperature taken twice a day. The aim of the officials of the camp is to know each patient intimately, and to encourage him to confide in them. His day at the camp is regulated and everything done to remove all worry and anxiety. He is kept under careful supervision. Such a camp may be readily attached to a hospital, and can be run at a moderate expense as has been proved by the Good Samaritan Hospital, in Boston, the past year. A day camp is of value as it removes for a time the source of infection from the community and the home; it enables some cases to obtain admission to a sanatorium which could not otherwise go; it enables cases to obtain proper care which, although suitable, for some reason cannot go to a sanatorium; it obviates in some cases the necessity; it helps to complete the cure in some cases which have been discharged from a sanatorium. It is also a value on educational lines. As to the permanent good which results I can only say that of the cases present at the camp in the season of 1905, one third are able to work all or a part of the day. One point which I would like to emphasize is the importance of a complete examination of all the members of a family in which there is a tuberculous patient. In this way we are enabled to detect the disease in the earliest stages, and to take proper steps to prevent its spread.

DR. A. C. GETCHELL, of Worcester: One other point should be touched upon at this time it seems to me. It

is the matter of ways and means. Dr. Pratt's results are very encouraging and his work is of great value. Can others in other places do as good work? He has the material resources of a large church and a well supported tuberculosis organization at his disposal. Looking to our work in Worcester we have neither; nor, so far as I can see, are we likely to have. On the other hand it is quite within the range of probability that one of our large hospitals may soon make proper provisions for poor consumptives. As a practical measure I think we will sooner provide suitable care for these unfortunate persons by putting our main energies upon utilizing the equipment of existing institutions with such slight additions as may be necessary. As has been said, Dr. Pratt's personality is an important element of his success. While this has contributed so largely to his work it cannot be counted on with definiteness in other places. To my mind the great value of his work, and I sincerely hope he will keep on with it, is a demonstration of what can be done at home with the moderately poor consumptives. But I feel that we shall make no material progress in caring for the very poor, the most dangerous class of all, until we provide adequate institutional care for them.

Dr. C. S. Millet, of Brockton: One word about the personality of Dr. Pratt, about which we have heard so much this afternoon. If there is anything in taking a real heart-felt interest in your patient, in paying attention to detail and insisting upon entire obedience on the part of the one most interested, which the rest of us can't imitate, then, of course, Dr. Pratt's personality is certainly the most important factor in the kind of work which he has originated.

Otherwise there is nothing about this work that any man here can't do.

MEDICAL INSPECTORS: THEIR FUNCTION.*

BY CHARLES HARRINGTON, M.D., BOSTON.

Yesterday there was passed by the Senate to a third reading, a bill, which already has passed the House of Representatives, entitled, "An Act to Provide for the Establishment of Health Districts and the Appointment of Inspectors of Health."[1] The bill was first reported in the House on May 1, by the Committee on Public Health, after full consideration of so much of the annual report of the Chief of the Massachusetts District Police as relates to the manufacture of clothing in tenement houses; so much of the Governor's address as relates to medical examination of minors in factories; a petition for legislation relative to the spread of tuberculosis; a petition for legislation to provide for the transfer of certain powers and duties of the inspection department of the District Police to the State Board of Health; a petition for legislation to provide for proper sanitation, ventilation and light in factories and shops and for the appointment of medical inspectors; a petition for legislation to prohibit overcrowding and bad air in factories and workshops; and a petition that medical inspectors be appointed throughout the Commonwealth.

Should the bill become law, it will be the duty of the State Board of Health to "divide the Commonwealth into not more than fifteen districts to be known as health districts, in such a manner as it may deem proper and necessary for the carrying out of the purposes of the [this] act"; and, this having been done, it will devolve upon the Governor to appoint in each such district "one practical and discreet person, learned in the science of medicine and hygiene, to be state inspector of health in such district." The appointees will hold office for five years, but may be removed by the Governor and Council at any time.

The duties of the inspectors will be so varied and extensive as to make the positions anything but sinecures, and in most districts their proper performance will demand of the incumbents practically their entire time and will involve constant travel from place to place. The bill provides, in the first place, that each inspector "shall inform himself respecting the sanitary condition of his district and concerning all influences dangerous to the public health or threatening to affect the same." This alone will be no small task, for although the area of the Commonwealth, in comparison with that of almost all other states of the Union, is small, the 15 districts together will include 33 incorporated cities and 321 towns, and each district, therefore, must contain a considerable population, divided among not a few distinct communities, large and small, urban and rural, manufacturing, agricultural, residential and mixed. In order, therefore, to inform himself and keep informed as to the sanitary condition of his district, and to carry out the duty with which he is specifically charged in the next clause, to "gather all information possible concerning the prevalence of tuberculosis and other diseases dangerous to the public health within his district," he must keep in touch with all of the local health authorities thereof, watch the incidence of communicable diseases in each city and town, inquire into their causes, be prepared to suggest preventive measures and to "take such steps as, after consultation with the State Board of Health and the local health authorities, shall be deemed advisable for their eradication."

Impressed with the value of the medical inspection of school children, the attention of his Excellency the Governor was drawn to the advisability of extending the same protection to minors employed in factories, under conditions which, in very many cases, are far more inimical to health than the conditions to which those confined for shorter daily periods in schoolrooms are subjected; and the matter was made the subject of an earnest recommendation in his inaugural address. If the bill becomes law, it will be the duty of each inspector to have an eye on all employed minors, to examine them as to their health, and, whenever advisable or necessary, to call their ill-health or physical unfitness to the attention of their parents or employers and of the State Board of Health. In some districts this duty will make large demands upon the inspectors' time, for in many manufactures large numbers of minors find employment in rooms where they are exposed to influences which tend

* Read before The Massachusetts Medical Society, June 11, 1907.

[1] The bill was enacted in both houses, and was signed by the Governor on June 19.

to break down their resistance to disease, and especially to tuberculosis.

A third duty imposed upon the inspectors is that of enforcing, under the direction of the State Board of Health and in place of the inspection department of the District Police, the provisions of existing laws relative to ventilation, light and cleanliness of factories; to providing suitable seats for women employed in manufacturing, mechanical, or mercantile establishments; to the employment of minors in the manufacture of acids; to proper water-closets for factories and workshops; to defective sanitary arrangements, drains and water supplies; to nuisances; to cleanliness, ventilation and provision for water-closets in public buildings and schoolhouses; to manufacture of clothing in dwelling houses and tenements; to providing pure water for employees; to installing hoods, suction pipes and fans or blowers where dry grinding on emery wheels is carried on; and to the maintenance of suitable dressing rooms and wash rooms in foundries. In other words, every manufacturing establishment, every public building and every schoolhouse will be under the sanitary supervision of the health inspector of the district in which it lies, and it will be the duty of that officer to visit each such place with reasonable frequency, to report upon its condition and to enforce the law relating to any defect or omission.

In addition to the duties specifically mentioned in the bill, the inspectors will be required to perform such other duties as the State Board of Health — under whose general supervision they will be — may from time to time determine. They will be required to keep records of their proceedings and observations, to submit annual reports to the board, and from time to time to furnish the board with information concerning conditions affecting the public health in their repective districts; and whenever they send written suggestions to local authorities they shall send copies thereof to the board.

From this brief résumé, one may well understand that for the proper and adequate performance of the various duties imposed upon them the incumbents of the positions must necessarily be men of good medical training and experience; of good physique, for the work will be arduous; of good judgment in sanitary matters, and endowed with that most necessary qualification, tact.

DISCUSSION.

DR. H. L. CHASE, of Brookline: I only rise to express a hope that members of the profession will make suggestions to the Governor as to the appointment of suitable men for these very important offices of inspector.

DR. W. J. SLEEPER, of Westford: I indorse what Dr. Harrington has said, and it seems to me that this matter of factory and health inspection should very properly be under the supervision of the Board of Health, and not under the District Police as it has been so many years. It is not the function of the police, and it has not always been carried out in the wise way it should be. While their intentions were good they lacked the necessary qualifications that scientific knowledge would give.

In answer to DR. HENRY JACKSON'S question as to whether much of the work could not be done by non-medical men, DR. HARRINGTON answered: An effort was made to induce the committee to strike out the word "medicine" and insert in place thereof the word "sanitation"; but inasmuch as the work of the proposed inspectors is very largely medical and requires medical training the committee declined to make the change and decided that the word "medicine" should be retained.

It is true that some of the work which the inspectors will have to perform can be done by others than graduates in medicine, especially that having to do with inspection of factories. As a matter of fact the graduate of an engineering school is likely to be a better judge of ventilating apparatus than the average medical man. The medical man knows when ventilation is defective, but may not know how to direct changes to bring about improvement. Again, it does not require a man skilled in medicine to point out that a given atmosphere is overcharged with dust and fumes. On the other hand, one of the most important duties of the proposed inspectors is to examine into the health of all minors employed in factories. Such an examination is beyond the power of the most gifted engineer, unless he has had a medical training.

It must be understood that this bill was based upon a large number of petitions indorsed by a number of different interests. In the first place, there were those who sought to take the factory inspection out of the hands of the District Police, and prominent among these were leaders of the labor unions, who asserted before the committee that until the inspection of factories was taken out of the hands of the District Police and put under men with scientific training they could not hope for sanitary improvement of factories. Other bodies interested were those working for the suppression of tuberculosis, and it will be noted that this disease is specifically mentioned in the bill, it being one of the duties of the inspectors to inform themselves concerning the prevalence of tuberculosis and other diseases dangerous to the public health, and to suggest methods of combating the same. There were others who for many years have wished to have the state divided into health districts, with medical officers of health such as are employed in a number of states, and in Great Britain and other foreign countries. Attempts so to divide the state have hitherto met with no success, and it would probably have been absolutely impossible to secure legislation appointing medical officers of health without a combination of interest such as came into being this year.

With reference to the point that it does not require a medical man to do some of the work of the proposed inspectors, let me call attention to the fact that there is in the bill a clause which empowers the State Board of Health to employ such sanitary experts as may be needed; this has reference to ventilation and other matters involving a knowledge of engineering.

DR. H. L. DEARING, of Braintree: In connection with what Dr. Harrington has said, I wish to say that in Braintree the inspection of the schools and factories has been carried on by three public-spirited physicians, and from our experience it seems very plain to us that the medical man is the only man who is fitted to make these inspections properly. In our investigations we have found that the floors of the factories are in very bad, in fact often filthy, condition. Before inspection the floors were washed up twice a year, now they are washed up twice a week. The danger of drinking out of the same cup is well illustrated by this example

which I will cite. One of the large employers of the town came to me with a sore on the lip, which he and I also felt sure came from using the same cup as the employees. He told me that after that he would see that there was proper medical inspection of his factory.

The chairman, DR. A. T. CABOT, of Boston: It seems to me that it is not only the duty of the members of the associated committees to recommend to the Governor capable medical men to serve as inspectors, but that it is also their duty to ally themselves with the inspectors when appointed, and to assist them in every possible way.

FACTORY INSPECTION.*

BY FRANK G. WHEATLEY, M.D., NORTH ABINGTON, MASS.

LEGISLATION to protect the public health has for many years been the settled policy of this Commonwealth. Every year the legislature enacts new laws or amends old ones. While in many cases changes in law have not notably improved conditions still the general trend of legislation has been helpful. Perhaps the last two or three years have been more than usually fruitful in protective legislation. The legislation leading to recent investigations of health conditions in industrial life by the State Board of Health has been of especial value, largely because of the intelligent methods of investigation adopted by the very able and efficient secretary of the board. Competent men were selected to do this work, and the commercial side of the problem, that is, the employers' interests, were duly considered. As a result of these investigations we have a certain amount of valuable information that may be made a basis for a more intelligent appreciation of the problem. The conditions discovered were in many cases fairly good, but in a discouragingly large number distinctly bad and, on the whole, the theory that a large number of municipalities have local boards of health, either incompetent or unwilling to do their duty, seems to be established. A necessary inference from this condition is that it is incumbent upon the Commonwealth in some way to come to the rescue, and it is hoped that pending legislation, of which it may be premature as yet to speak, may accomplish a great deal along this line. Factory inspection as a phase of the general health question is every year becoming more important. This because not only is the total number of factory employees increasing but the small workshop employing comparatively few people is giving place to the mammoth plant where thousands work under the same roof.

I propose to consider briefly the three groups of people which the subject naturally suggests and the effects of such grouping upon the general subject. These groups are (*a*) Employers; (*b*) Employees; (*c*) The General Public.

To the employer of labor factory inspection has in many cases come to be looked upon with disfavor. Arbitrary regulations enforced by ignorant and tactless inspectors, the interference with one's private affairs and additional expense are probably the most potent reasons for this state of affairs. I do not believe that the average employer objects to the establishment of reasonable sanitary regulations. He is too intelligent a man not to know that the employee whose environment is all that it should be in regard to pure air, proper temperature, proper light, proper toilet accommodations and freedom from exposure to contagious disease is of more value to him than the employee whose environment is unhealthy. I believe that the average employer, if approached in the right way, will prove a help rather than a hindrance to efficient factory inspection. In other words I think he needs education along health lines rather than additional legislation. Added to his interest as a manufacturer is his interest as a large tax payer in the general health of the community. In many cases the nature of the work done in the factory is such that under the most favorable conditions health is somewhat endangered; but I am inclined to believe that the so-called dangerous employments have been unduly advertised, and that inventive genius has and will continue to minimize the evil. There are, however, certain obstacles to the production of ideal health conditions in thickly settled communities that are well nigh insuperable under present conditions. I refer to the disposal of waste in communities where sewerage is not furnished by the municipality. My attention has recently been called to a case of this kind where an ideal handling of waste by the manufacturer would be so expensive as to be prohibitive. In such a case great care should be exercised to so handle the matter as to command the approval of intelligent public sentiment.

The employee is, of course, theoretically in favor of rigid factory inspection, and is, I think, as a rule willing to do his part to make it a success. Quite a large percentage, however, while apparently taking delight in seeing the employer compelled to spend money for sanitary appliances, are the first to abuse the facilities given them. Then, too, restrictions in cases of contagious disease are likely to prove unpopular. Here education along sanitary lines is also needed.

To the public factory inspection is of vital interest. The enormous expense which poor health brings upon the community, to say nothing of the humanitarian side of the question, should awaken the interest of every public-spirited citizen in the subject. Then, too, the product of the factory has in so many cases a bearing upon the health of the consumer that the public cannot afford to allow it to be prepared under unhealthy conditions. I want to impress upon every medical man present the importance of the subject, and to suggest that you can by your personal efforts do a great deal to popularize and make effective scientific factory inspection. The medical man above all others is in a position to educate public sentiment along such lines. If the Commonwealth is to inaugurate an efficient factory inspection it must have an enlightened public sentiment in favor of such inspection.

In the crusade against tuberculosis now so well under way in the state, intelligent factory

* Read before The Massachusetts Medical Society, June 11, 1907.

inspection is an important factor. The state has just made a large appropriation for hospitals for the treatment of tubercular patients. Let us hope that in another decade we shall have so lessened the number of those thus afflicted that the hospitals will be poorly patronized.

It is interesting in this connection to note the work that is being done outside the state along the same lines. Pennsylvania has just appropriated one million dollars with which to fight the white plague, and even our diminutive neighbor, Rhode Island, comes bravely to the front with an appropriation of three quarters of a million. With the work done in Germany recently you are all doubtless familiar. There seems to be a general awakening all along the line, and it is for us, the medical men of the old Bay State, to see to it that our beloved Commonwealth is in the very forefront of the battle.

DISCUSSION.

The Chairman, DR. A. T. CABOT, of Boston: The subject of factory inspection is now before us for discussion and is one which we should all consider carefully on account of its effect in prevention of tuberculosis. We should urge adequate factory inspection and try to enlist the help of employers to obtain it. Rhode Island has taken steps toward factory inspection which I think we might study with interest and profit. In their experience with factory inspection they have found that one of the most satisfactory inspectors is the foreman who is always in the workroom with the hands. He does not know all the symptoms of consumption, perhaps, but he knows a cough when he hears it, and after hearing a man cough day after day, he is able to advise such a man to go to the doctor for examination. It is the cases which are early discovered which can be sent to a sanitarium. Those are the cases which come back to the factories, and are living examples to the workmen of the value to them of factory inspection.

DR. C. S. MILLET, of Brockton: In the city of Brockton during the past six months I have been trying to carry out this line of work in the so-called Walk-Over Shoe Factory, and all parties concerned — that is, the members of the firm, the superintendents of the different factories and the employees — have been willing and even anxious to aid me in every way.

In talking to the foremen, I have tried to tell them what to look for in their efforts to determine whether or not a man is probably affected and should have his lungs examined. The objective symptoms which seem to be most frequently the result of a tuberculous infection are four in number, and named in order are, hemorrhage, cough, emaciation and pallor.

First, hemorrhage: Any spitting of blood, no matter how slight, should always be sufficient grounds for a careful physical examination. Persons who raise blood are quite apt to conceal it, if possible, probably because of the curiosity and excitement which the sight of blood always arouses; hence, the foremen should always follow up the scent if they perceive any blood upon the floor anywhere about the factory.

Second, cough: Osler has said that a cough which lasts over three weeks is very suspicious; and certainly if this symptom, even though it may be insignificant in character, shows the least tendency towards chronicity, the origin must be determined.

Third, emaciation: If a man is thinner than he should be compared with his height, or if he has recently lost weight to an appreciable degree without apparent cause, then again it is of the greatest importance to discover whether or not he has tuberculosis.

Fourth, pallor: This symptom one should always consider at any rate suggestive enough to demand an explanation. It may be due to an actual anemia, as shown by the test for hemoglobin, or it may be caused by an unnatural condition of the circulation through the skin; and in either case the cause is so often tuberculosis that a physician must be absolutely certain as to its source before he can exclude the disease in question.

In conclusion, I would like to say that this work of seeking out cases of tuberculosis among mill and factory operatives must always be done with caution and sometimes even with secrecy, in order not to make it possible for the other hands to shun or ridicule a fellow-workman who has been subjected to an examination.

DR. W. J. SLEEPER, of Westford: I think that factory inspection will do a great deal to blot out the great white plague in that it will call attention early to any trouble in the chest; and I think also that it is very important to secure the co-operation of the employee.

The increase in speed in the factories, while it produces an increase of production, is certainly a detriment to the employee, and I see no way of correcting the condition except by means of the two weeks' vacation in the summer time. It seems to me that the giving of vacations for the purpose of recreation and change of scene should be encouraged by our Society.

DR. ELEANOR WAY-ALLEN, of Walpole: In Walpole a committee has been formed for the relief and control of tuberculosis, and we have found that people co-operate with us very well. We have put up "No Spitting" signs and are recommending men and women to physicians if we find they are failing in health. The largest employer has a physician at his own expense to examine patients. We have found that working with the foremen is a very successful method.

DR. J. C. PITTA, of New Bedford: In New Bedford, as you all know, there are many large factories, and they are a long way from the most progressive methods of fighting this disease. There is not a great deal of inspection. A large number of the people come from my country (Portugal). Last year there were over 120 sent back because they had tuberculosis. I tried to organize a society for the protection of our people, and we have succeeded in doing something. Some of them have been sent to the State Sanitarium at Rutland, and the bills paid by our Society. We have a nurse who goes around and takes their temperatures and gives them good advice. We think we have done much work, but could do more if we had the assistance of other societies.

I am also a member of the District Committee in New Bedford, and for quite a number of months we have not had a meeting, due mostly to the fact that the president of the committee was sick, and afterwards was so busy that he could not give the time to it, and we got somewhat discouraged. Still we have done quite a good work after all. We succeeded in getting a tuberculosis exhibit in City Hall, and it was attended by quite a large number of people of the community. Most of the patients sent back to the old country and most of the patients attended by this society have been mill hands. Many of them drink from the came cup, and they are constantly in a dusty and overheated atmosphere.

IT is reported that several cases of anthrax have been discovered among the cows in dairies in Orange County, N. Y., and that a number of cows have died of the disease. The state veterinarian has ordered the isolation of all cattle exposed, and is making great efforts to stamp out the disease.— *New York Med. Jour.*

Boston City Hospital.

CLINICAL MEETING OF THE STAFF, DEC. 20, 1907.

A CASE OF MULTIPLE OPERATIONS FOR ABDOMINAL ADHESIONS.

BY F. B. LUND, M.D.

L. R., aged thirty-six, colored, had been operated upon in Philadelphia eleven years ago for uterine fibroids. Three years later she was operated upon at the Roosevelt Hospital in New York, for acute obstruction by bands, and again, soon after that, for chronic obstruction. Five years ago she was operated upon for a large ventral hernia by the writer, and soon afterward by Dr. J. C. Munro, for chronic obstruction, due to adhesions. Dr. Munro had some difficulty to find any free abdominal cavity to work in, owing to the extent and character of the adhesions, but finally was able to make a Murphy button anastomosis between the lower part of the ileum and the sigmoid. This operation relieved her so that she was able to go back to work. She enjoyed fair health and worked as a cook until recently, when she was sent to the hospital by Dr. Courtney, suffering from abdominal pain, distention and constipation. I operated upon a small ventral hernia in the right iliac region without relief. Her distention and discomfort continue, and further operation is proposed in a few days.

A few days later this was performed. The entire lower abdomen was found filled with intestines adherent to each other and to the abdominal wall, so that no real abdominal cavity could be gotten into until the incision was carried into the epigastrium along the border of the left rectus. Only about two feet of free intestine was found, starting from the beginning of the jejunum. With great pains and care, separating coil from coil and fold of mesentery from fold, about seven feet of the small intestine were freed. The loop of the sigmoid was found, but appeared to be obstructed at the pelvic brim, so that anastomosis with this, it was thought, would be unsatisfactory. The lower sigmoid and upper part of the rectum were so buried beneath the coils of small intestine, that it was impossible to free and bring them up. The finger introduced as high as possible per anum passed the valves and seemed to enter the lower sigmoid. At any rate, as far up as I could reach, the rectum was unobstructed, even somewhat dilated. The half of a Murphy button was carried up as far as possible into the rectum in a pair of long curved clamps, and by making the rectal wall prominent with this, it was possible to dissect the coils of small intestine away from above so as to come down upon it. The other half of the button was then introduced into the lowest coil of small intestine, which had been freed, about seven feet from the beginning of the jejunum, and the rectum was cut from above, so as to let the inner cylinder of the button project through it. Then by pushing down the upper half of the button, it was possible to effect an ileo-rectostomy in the bottom of the pelvis without sutures and with a minimum of soiling. It was recognized that by this procedure the entire large intestine was placed out of commission, and possibly hardly enough small intestine left to maintain nutrition, but it was necessary to get by the obstruction, and this was the only way to do it, except by an enterostomy, and the disadvantages of a permanent enterostomy of the ileum are too obvious to dwell upon. The abdomen was sewn without drainage. The wound was a long one along the outer border of the left rectus. The veins supplying the rectus were found and left intact.

The patient did well at first, and the distention was relieved, though she had three or four liquid movements a day, owing to the loss of the drying function of the large intestine. The button was passed in about two weeks. After about a month distention and vomiting appeared and rectal feeding had to be resorted to. This was tolerated for a short time only, and then small amounts by mouth were begun. Now (Feb. 15) there is no distention, the patient is being fed by mouth, and seems to be improving a little. The recent distention is undoubtedly due to the tying up by adhesions of the little bowel she has left. No further operation seems possible, and the question of her ultimate survival, with the limited amount of badly crippled intestine she has left, seems rather likely to be decided against her.

TWO CASES OF INTRALIGAMENTOUS FIBRO-MYOMA OF THE UTERUS, AND THE METHOD EMPLOYED TO CONTROL BLEEDING FROM THE BED OF THE TUMOR IN THE BROAD LIGAMENT.

BY C. M. GREEN, M.D.

Case I. J. B., aged fifty, had had two children and three miscarriages. For three months she had had irregular, profuse uterine hemorrhage; and for two months obstinate constipation, obviously due to the pressure of a fibroid tumor which completely filled the pelvis. At operation a sessile growth, two to three inches in diameter, was found at the right cornu, the corpus uteri was of about normal size, but growing from the supravaginal cervix was an intraligamentous mass as large as a fetal head. The broad ligaments were laid open and the tumor removed with great difficulty. There was considerable oozing from separated adhesions. Some surgeons control bleeding in these cases by gauze pressure-drains, an opening being made into the vagina for removal, and the gauze covered in by closing the peritoneum. The reporter believes that a better way is to secure hemostasis, and at the same time to obliterate the cavity in the broad ligaments, by applying several tier sutures, and this method was followed in the two cases reported.

There was no post-operative hemorrhage in this case; but the patient died of shock and exhaustion on the second day.

Case II. J. L., thirty-nine, single, had a large, multiple-fibroid uterus extending above the umbilicus, and the chief symptom was pain. There was a large, intraligamentous mass growing from below the peritoneum; this was enucleated, supravaginal amputation of the uterus was done, the broad-ligament cavity was obliterated by suture, and covered with peritoneum. This case has made an uninterrupted recovery, and will be discharged in a few days.

Dr. Green also showed an unmarried girl of eighteen, on whom he had operated, whose case was interesting from its rarity, — procidentia of the uterus in a nullipara. Two years previously, when sixteen years old, she had lifted a wash-boiler filled with clothes, and as a result, apparently, she suffered prolapsus uteri, so that the cervix protruded from the vulva. After unsuccessful treatment with pessaries in the Out-Patient Department, she entered the hospital, when the uterus was found retroverted and retroflexed, and it protruded from the vulva on straining. It was thought best to perform ventral suspension. At operation both ovaries were found cystic, and were resected. After the usual convalescence, examination shows, with the patient in the erect posture, that the uterus is in normal axis and position.

Referring to the subject of the conservative surgery of the ovaries and Fallopian tubes, Dr. Green reported a case from his service, on whom

he had operated in 1903 and 1904, and whose subsequent history he had recently learned:

R. F., aged twenty-nine, married six years, IV-para, entered the hospital Nov. 16, 1903, on account of backache and constant vaginal discharge. The uterus was retroverted, the right tube swollen, and the cervix torn. Curettage and bilateral trachelorrhaphy were performed, and the patient was discharged, apparently well, on Dec. 7.

Twelve days later, the patient returned, on account of pain in the left lower abdominal quadrant, and a diagnosis of salpingitis was made. At this time the husband acknowledged that he had gonorrhea. The abdomen was opened, and the left appendages were removed. The right tube, although swollen and congested, was pervious, and it was left *in situ*. The cystic right ovary was resected, the uterus was suspended, and the patient was discharged well, Jan. 31, 1904. It was thought at the time that the patient ran some risk of a second laparotomy by the conservative treatment of the right tube and ovary, and in view of the obvious Neisser infection.

The subsequent history of this patient is as follows:

She menstruated on March 18, 1904, and on Dec. 15 of the same year she gave birth to a full-term child, without any complication from the suspension of the uterus. Last June, eighteen months later, another child was born; and at the present time, although somewhat debilitated by lactation, the patient is entirely free from pelvic symptoms.

In this case conservative treatment of diseased appendages was successful; in some cases it is not. But is it not better occasionally to perform secondary laparotomies than to deprive young women of all hope of maternity, when even small portions of ovarian tissue may be left *in situ*, and when a tube, although not entirely healthy, may yet perform its function?

CANCER OF COLON.

BY FRANKLIN W. WHITE, M.D.

Male, aged thirty-six, good family history; operated upon for piles two years ago. For last eight months indigestion, occasional vomiting or regurgitation immediately after meals; epigastric distress occasionally relieved by food. In last month pain in right navel region; bowels loose of late. Best weight, 204; loss of 43 lb. in last few months.

Test of gastric secretion and motility show normal motility and secretion normal (free HCl, 43; total acid, 60) or increased (free HCl, 60; total acid, 98). The usual treatment for hyperacidity had relieved the symptoms somewhat.

I saw patient first on March 13, 1906; examination showed a large, vigorous man, slightly pale. A deep rounded solid mass, size of an apple, was found just above and to right of navel, slightly tender and movable, not felt bimanually in flank; liver, edge easily felt, not continuous with tumor. One examination of feces for blood on meat-free diet was negative. Diagnosis of probable cancer of bowel was made and patient referred to Dr. F. B. Lund, of Boston, for operation. At operation a cauliflower cancer was found encircling the ascending colon five inches above the cecum, with few secondary glands in the mesentery. The bowel and glands were resected and a side-to-side anastomosis made. Recovery was uneventful.

Patient had gained 40 lb. in the nine months since operation, has worked hard and steadily, had practically no digestive symptoms. He considers himself well.

The interesting features of this case are the brilliant immediate results of operation and the association of abdominal cancer with gastric hyperacidity. The unusual position of the tumor of the lower part of the ascending colon is explained by the adherence of the omentum to it, which dragged it upward and toward the median line. The single negative guaiac test of the feces for blood shows the need for repeated examinations in suspected cancer of the bowel. Curiously enough, positive results of the blood test are decidedly less constant and frequent in cancer of the bowel than in cancer of the stomach. Cases reported by Boas and Ewald confirm this observation, but no one has explained it.

GASTRIC ULCER.

BY FRANKLIN W. WHITE, M.D.

Male, aged forty-six. For two years he had had distress or pain two or three hours after meals; occasional vomiting; gradual loss of weight. In last three weeks there was much epigastric pain; frequent vomiting of small amounts of "coffee ground" material. Patient was pale, emaciated, very weak; had recent rapid loss of weight, 25 lb. in all. Hemoglobin, 65%; reds, 3,000,000. At first visit vomited a pint of typical "coffee ground" material, containing abundant free HCl.

Gastric contents after test meal, 150 cc., free HCl, 63; total acidity, 90; guaiac positive. Epigastrium diffusely tender; no tumor; 500–800 cc. of brownish fluid containing free HCl and digested blood were vomited on two occasions before breakfast.

The man's whole appearance, anemic, cachectic; the "coffee ground" vomiting, the gases and excess of fluid in the fasting stomach suggested cancer, and this diagnosis was made by two experienced physicians. The abundant reaction of HCl favored ulcer, or the early stage of a cancer developing upon an ulcer base (we know that this is the only form of cancer in which hyperacidity is likely to persist). This second diagnosis seemed to best explain the symptoms, the early distress, pain and vomiting at the height of digestion (ulcer), and the late, rapid loss of weight and strength, anemia and "coffee ground" vomit (secondary cancer). The treatment was rest in bed; exclusive rectal feeding first week; liquids and soft solids by mouth next four weeks; no meat extracts were given. The feces were examined frequently for blood by the guaiac test, with the following results:

Nov. 20, positive,	Dec. 8, negative,
Nov. 26, positive,	Dec. 12, negative,
Nov. 28, positive,	Dec. 13, positive,
Nov. 29, positive,	Dec. 15, negative,
Nov. 30, negative,	Dec. 17, negative,
Dec. 1, positive,	Dec. 19, negative,
Dec. 3, positive,	Dec. 23, negative and negative thereafter.

The intermittent appearance of the blood in the feces was very strong evidence in favor of ulcer and against cancer. The diagnosis of simple ulcer was finally made and justified by the consequent history.

The patient gained 20 lb. in the next few months; has worked steadily during the past year and felt perfectly well, except for brief attacks of hyperacidity, which are promptly relieved by appropriate diet, olive oil and alkalies.

The especially interesting features in this case were the valuable aids in diagnosis, given by the

guaiac test of the feces for blood and the good immediate (one year) result of medical treatment.

The presence of a large amount of fluid in the fasting stomach was not due to organic pyloric stenosis, but evidently to hypersecretion, or possibly to stasis of fluid from pyloric spasm.

Reports of Societies.

AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-second Annual Meeting, Held at Washington, D. C., May 7, 8, and 9, 1907, in Conjunction with the Congress of American Physicians and Surgeons.

The President, Dr. Clement Cleveland, New York, in the Chair.

METASTATIC CARCINOMA OF THE TUBE AND OVARY IN CANCER OF THE CERVIX UTERI.

Dr. Fred J. Taussig, of St. Louis, Mo., read a paper on this subject, in which he concluded that mild chronic inflammatory conditions of the tube and ovary were frequently met with in cancer of the cervix. Whether this was merely a coincidence or not, he would be unwilling to say. On the other hand, cancerous metastases in these organs were extremely rare in cervical cancer. In fact, he could find no record of such metastasis in an operable case. In carcinoma of the body, however, they were not infrequently seen in tube or ovary, or both. Hence it would seem logical to advise the removal of both tubes and ovaries in every case of cancer of the body. If, however, the patient was still five or ten years from the time of the menopause, and the site of the cancer be in the cervix, the saving of one ovary would be attended with practically no risk to the patient and might relieve her of the disagreeable symptoms of the premature menopause. Since this could be done without interfering with the complete removal of the lymphatics directly tributary to the cervix he believed it logical to leave one ovary, or a portion of one ovary, in every operation for cervical cancer in a woman under forty years of age.

DISCUSSION.

Dr. J. Wesley Bovee, of Washington, D. C., said metastases in cancer of the uterus were by no means common, and that as the disease spread metastases occurred. This emphasized the fact that in the cases brought to the attention of the gynecologist he was helpless in the treatment of cancer of the uterus; that in the cases in which the conditions would ordinarily offer great hope of success we would find that metastases occurred in those structures which we would not remove, the result being that cancer recurred or continued unsuspected. At best, the treatment of cancer of the uterus was not hopeful, notwithstanding the claims of radiographers and the demonstrators of radium, etc., and those who did the most radical surgical operations. He was not prepared, in the present light of surgery of cancer of the uterus, to accept the suggestion of the essayist, that it was safe to leave a portion of an ovary or even one ovary in extirpating cancer of the uterus. His own conviction was that the operation should be as radical as it could be consistent with saving the life of the patient.

Dr. Lapthorn Smith, of Montreal, reported a case of cancer of the cervix in which operation was done early by another surgeon, with every possibility of a complete recovery of the patient and freedom from recurrence; yet this woman came to him a year later, with no sign of recurrence in the vagina, but with two distinct masses in the ovaries which could be readily felt. He considered it too late to do anything in an operative way. This case made such an impression on him that ever since, when doing vaginal hysterectomy, he always removed the tubes and ovaries. He did not think it was safe to leave an ovary or a piece of an ovary, when there was such a tremendous risk of recurrence.

Dr. Reuben Peterson, of Ann Arbor, Mich., desired to place himself on record as voicing the sentiment of Dr. Bovée against the leaving of one ovary, or part of an ovary, in the operation for cancer of the uterus. This was a step backwards, and was not in accordance with progress that had been made in the last ten years in the treatment of cancer of the uterus. He was not convinced that the leaving in of one ovary after the removal of the uterus helped the patient, so far as the menopausal changes were concerned. He had been unable to see much, if any, difference where an ovary had been left in and where it had been removed, after the removal of the uterus for cancer.

Dr. Walter M. Chipman, of Montreal, doubted whether it was a wise thing to leave even one ovary, or even a part of one, after the removal of the uterus for cancer, no matter where the cancer was situated. While it was true that the ovary was not in the direct path of the lymphatic distribution of the pelvis, yet so great and so rich was the anastomosis that he thought the leaving of ovaries must always be a risky procedure.

Dr. Taussig, in closing the discussion, said he anticipated that most men would hardly agree with him as to the advisability of leaving a portion of an ovary in the class of cases under discussion; but he believed, however, from the statistics that the procedure was not at all unsafe, and it seemed to him that it was just as logical to advise the removal of the appendix as to advice the removal of the other ovary. The appendix was a useless organ; the ovary — at least in the opinion of some — helped to make the menopausal disturbances less severe in women under forty years of age, if left.

A NEW METHOD OF VERSION.

Dr. A. F. A. King, of Washington, D. C., spoke of the correction of transverse presentations by the hitherto unrecognized factor of thigh-pressure upon the abdomen, induced either (1) by posture, or (2) by manipulating the lower limbs. The former, he said, was Nature's method of preventing and correcting cross-presentations; and in primitive races was daily exercised by the squatting posture during defecation, etc. Squatting was not a symmetrical proceeding; the two thighs did not press equally. One foot was flat upon the ground and in advance; the other, in the rear, rested only on its toes. The thigh of the front foot would press high up upon the breech end of the fetus; the thigh of the rear foot would press low down upon the head forcing it from the iliac fossa into the pelvic brim, as was illustrated by diagrams.

THE SUPERIORITY OF PRIMARY OVER SECONDARY CESAREAN SECTION; FEASIBILITY AND ADVANTAGES OF A PREDETERMINATION OF THE METHOD OF DELIVERY.

Dr. Edward Reynolds, of Boston, spoke of primary operations being determined upon in advance of labor and performed at an elected date, or with the advent of the first pains. Secondary operations may be performed as soon as a test in labor had shown that the natural powers were likely to fail and before serious exhaustion set in. Late operations were considered in

the light of a last resort. Late sections were already discredited; while secondary sections were still the most frequent class. He gave the statistics of primary, secondary and late sections of the last ten years. Primary section was a very safe operation; while secondary section was only moderately safe. Late section was attended with a high mortality. In general, the mortality was roughly proportionate to the amount of labor endured before operation. Decision before labor was a matter of great moment. The doubtful cases were constantly narrowing and should be done away with. Accurate prediction of expected difficulty required: estimation of the shape and relation of the pelvis (measurements alone were entirely unreliable); of the probable muscular character of labor; of the size and ossification of the head. Methods of estimation of the maternal obstacles required knowledge of the maternal powers (these could be foretold with considerable accuracy); and of the mechanical character of the head. He emphasized the value and importance of obtaining a previous history in multiparæ.

He submitted the following classification: (*a*) undoubted Cesarean section cases; (*b*) cases clearly capable of delivery without the Cesarean; (*c*) doubtful cases.

As to the treatment, in Class A he would resort to primary section; in Class B, labor and the intrapelvic operations. In Class C, a final examination under ether at the date of election, the method finally decided on, and decision adhered to. The predetermination of methods was work for experts only. Lastly, he pointed out that a more friendly relation between the specialist and the general practitioner was desirable.

PUBIOTOMY.

DR. HENRY D. FRY, of Washington, D. C., read a paper on this subject. Pubiotomy was a satisfactory operation, so far as the operation itself went, for enlarging the pelvic girdle in moderate degrees of pelvic contraction. It was easy to perform and could be employed in simple flat pelves with a conjugata vera of 7 or 7½ cm. Separation of the severed bone for 4 or 5 cm. was usually sufficient to enable easy extraction with forceps.

The principal objection to the operation was the difficulty encountered in the after-treatment. These difficulties were little, if any, less than those which brought symphysiotomy into disrepute. The pelvis must be immobilized and the patient kept in the dorsal position several weeks. Maternity institutions could overcome the objection to a large degree by the use of a special bed, as the hammock suspension bed described by Ayres. Williams used the Bradford frame after two of his operations. Jewett employed an ordinary hospital stretcher "the poles of which were lashed to the top rails of an iron bedstead. A trap-door was provided for the dejecta." Montgomery recommends a pelvic sling suspended from the ceiling and attached to a compound pulley. Ordinarily, after pubiotomy and symphysiotomy, the evacuations of the bladder and bowels were attended with discomfort, and it was a hard task for the nurse to keep the parts clean, which was the more important after secondary operations where the patient was already septic and the soft parts contused and lacerated. In consequence, therefore, of the unsatisfactory convalescence after pubiotomy, the operation would obtain in this country a limited field of usefulness as an elective operation. Cesarean section offered a substitute free from this objection and its indications would be extended to embrace these cases of minor degrees of pelvic contraction. With a head movable above the inlet, and one which will not descend by suprapubic pressure, that operation should be performed primarily. When the head was moulded and engaged, forceps might be tried tentatively before resorting to section.

The indications for pubiotomy may be stated as follows: A living child and some contra-indication to Cesarean section. The usual conditions presented were: a moderate degree of pelvic contraction, which had been unrecognized generally, ineffectual efforts employed to deliver with high forceps, the woman exhausted, and infection probably started. If the child be dead, craniotomy; if alive, pubiotomy, in spite of the objections raised against it. It was better to have a live woman at the end of a tedious convalescence than a dead one after a "successful" operation.

INDUCED LABOR AND DELIVERY BY ABDOMINAL SECTION.

DR. EDWARD P. DAVIS, of Philadelphia, said that among obstetric operations there was none which in selected cases gave better results than the induction of labor. This was especially true in disproportion between mother and child whether caused by pelvic contraction, excessive fetal size, or prolonged pregnancy. Private patients were especially benefited by this operation, as they usually came early under the care of the obstetrician and gave him a better opportunity to study their cases than did hospital patients. Private patients who had passed through a disastrous first confinement were often safely delivered in subsequent labor by the induction of labor. Experience, however, and the study of statistics showed that induction of labor was not without serious disadvantages; it was a process uncertain in duration, often exposing the patient to considerable loss of rest and to prolonged suffering. Labor was rarely terminated without some active interference, and this was most often to be accomplished through a cervix poorly prepared for dilatation. Some of the methods employed to terminate induced labor produced unfavorable presentations and positions of the fetus, increasing the risks to mother and child. While it is possible, considering the interests of the mother first, to have a low mortality and morbidity rate for her, the best results so far published gave a very considerable mortality and morbidity for the infant. He believed that the induction of labor compared in gravity, when the interests of both mother and child were considered, with other major obstetric operations.

The author then cited six cases to illustrate the statements he had made.

He strongly urged the importance of conducting cases of induced labor in such a manner that the patient shall be in favorable condition for a major operation, if necessary. He did not believe it justifiable during induced labor to make efforts at delivery by forceps or version unless the conditions were such as to make it reasonably certain that these operations will be immediately successful. If engagement of the head did not develop during induced labor the use of the forceps was a dangerous procedure. If the operator was sure of the size and contour of the pelvis, and reasonably certain of the comparative size of the fetus, version, where the head did not engage, was the safer operation. The writer would not resort to delivery by section in a case where efforts at delivery by forceps or by version had been made. He believed that with careful antiseptic technique it was possible to introduce bougies within the uterus, or even to employ dilating bags without infecting the patient. These procedures should not cause lacerations and should not essentially wound the epithelia of the genital tract. It was impossible, however, to make tentative traction with forceps, or to practise the manipulations necessary in attempting

version without producing lesions in the genital tract through which infection might enter. It was his practice then to decline celihysterotomy in all cases where forceps or version had been tried.

In severely septic cases, the child being dead and unsuccessful efforts having been made at delivery, he believed that the Porro operation would give the best results. In cases where forceps or version had been tried without success, if the child was living, he believed that the consultant should again try whichever of these procedures he thought best, utilizing Walcher's position if advisable; failing in these craniotomy should be done.

As to pubiotomy, a sufficient number of cases had been published to show that the operation, like all other surgical procedures, was not without its dangers and disadvantages. A maternal mortality of from 5 to 7% and a fetal mortality of 17% indicated its severity.

As to delivery by abdominal section, all things considered, and especially when the fetal mortality was taken into consideration, the claims of abdominal section for safe delivery of mother and child could not be disregarded. He did not believe that at the present time a dogmatic opinion could be formed concerning any one method of delivery. Another factor of importance was the value placed by parents upon the life of the child.

DISCUSSION.

The papers of Drs. Reynolds, Fry and Davis were discussed together.

Dr. Egbert H. Grandin, of New York, said the conclusions and line of argument advanced by Dr. Reynolds were in accord with those which he presented in a thesis read before the society seventeen years ago entitled, "A Plea for the Elective Cesarean Section." He contended then that this operation was ideal and although seventeen years had elapsed since, he had not seen fit to change his position.

As to pubiotomy, he would advise it in preference to symphysiotomy, although he had not done the former operation, but had performed symphysiotomy twice, with living mothers and living children, and, so far as he knew, with no disability on part of the women.

Dr. Lapthorn Smith, of Montreal, condemned pubiotomy. Last summer he performed two Cesarean sections, and could testify to the surprising ease with which the operation was done in both cases.

Dr. James Clifton Edgar, of New York, was uncertain as to where to draw the line between Class A, and Class B, in the cases discussed by Dr. Reynolds, that is, the antepartum cases, and the early intrapartum cases. It occurred to him that if Class B or the early intrapartum class, was moved a little forward, and the women not allowed to stay in labor quite so long, instead of a mortality of 3% as reported by Dr. Reynolds, it would approach 1% in the antepartum cases. Where Cesarean section was undertaken in the latter part of pregnancy there was difficulty in securing good drainage.

Pubiotomy did not appeal to him, although he had never done it. He had, however, done six symphysiotomies.

Dr. Robert A. Murray, of New York, thought that eventually, in the vast majority of cases, obstetricians would gradually come to the point where they would let women go to labor prepared to do a Cesarean section, and not interfere with high forceps, or version, or any other method that would produce traumatism of the cervix and possibly cause infection which would defeat the result to be gained from a clean Cesarean section.

Dr. Robert L. Dickinson, of Brooklyn, N. Y., said the only Cesarean section case he lost was a young woman who suffered from toxemia throughout her pregnancy. She was operated on at the beginning of labor pains, but gradually died from a lack of resistance after an easy Cesarean section. For many years obstetricians had had control of the second stage of labor, and with Cesarean section, forceps and version the obstetrician could do what he chose. But the obstetrician had stood helpless before the difficult dilatations and before badly developed cervical conditions. He thought it was unobstetrical to insert a bougie into the uterus as it might loosen the placenta and carry infection. We could not be sure of absolute cleanliness.

The papers were further discussed by Drs. E. W. Cushing, of Boston; George Gellhorn, of St. Louis, Mo.; Seth C. Gordon, of Portland, Me.; Malcolm McLean, of New York; Willis E. Ford, of Utica, N. Y.; Philander A. Harris, of Paterson, N. J., and the discussion closed by the essayists.

OVARIAN PREGNANCY.

Dr. J. Clarence Webster, of Chicago, presented a specimen of ovarian pregnancy. The case was almost identical with the one he reported three years ago, though more interesting, in that the embryo was in position in this specimen. One could see the amniotic cavity with the embryo in position. The thickness of the ovarian tissue averaged about half an inch, except the placental area, where it was thicker. There were several hemorrhages in the ovarian tissue, especially in the position of the placenta.

UNIQUE SPECIMEN.

Dr. Webster presented another specimen which he obtained two years ago while on a vacation in New Brunswick from Drs. White and Ferguson. The patient from whom the specimen was removed was a man, thirty-three years of age, who was admitted to the hospital with symptoms of acute peritonitis. He had had for many years an irreducible scrotal hernia, and it was supposed there was strangulation. The man had been kicked by a horse. An incision was made in the left inguinal region; no hernia was found, but a structure which looked like an adult uterus, tubes and ovaries. The uterus was removed, and what appeared to be a cervix. It was adherent around the inguinal ring; the abdomen was rapidly opened, the patient being practically moribund by that time. The incision was closed, and nothing more was done. Patient died. The specimen was given to Dr. Webster, and he had carefully worked it up. On first presentation it seemed like the adult female genitalia, but careful dissection and microscopical study disclosed uterus and tubes, and what appeared to be ovaries were testicles, but which occupied exactly the same position as the ovaries in the female. The mucosa resembled that found in the adult female. Microscopical examination showed the glands were complex. He emphasized particularly the adult uterus. The tubes had the characteristics of those of an adult female, except the fimbriæ were not so complex. There were fewer fimbriæ; but the relationship to the testicle was exactly the same. On one side there was more marked ovarian or testicular fimbria. On examination of the broad ligaments he found on one side there was a cyst. Both round ligaments were present, but on the side on which the cyst existed the round ligament was flattened out and thin. On careful dissection of the broad ligaments there was a marked tube, about 4 mm. in diameter, slightly convoluted, extending from the upper inner portion of the broad ligament towards the cervix. It was quite firm and had the consistence of a pipe-stem. He pointed out the Wolffian duct, and the vas deferens, also the cervix and prostate. The patient was the father of twin children.

DISCUSSION.

Dr. E. W. Cushing, of Boston, narrated the case of a man, operated on for hernia, in which a uterus was found in the hernia.

Dr. Thomas S. Cullen, of Baltimore, said that some years ago in Baltimore there was found at autopsy in a child a complete set of both female and male pelvic organs.

THE CARE OF THE WOUND AND THE AFTER-TREATMENT OF LAPAROTOMIES.

There was a symposium on this subject.

THE METHOD OF CLOSING THE WOUND.

Dr. Seth C. Gordon, of Portland, Me., read a paper on this subject. He spoke of the time required for perfect union of abdominal wounds, and also pointed out the necessity for using such sutures as can be retained at least two weeks without absorption. He emphasized the use of suture material which is not absorbable and which can be removed at the end of two weeks, as well as the use of suture material that was least liable to infection.

(To be continued.)

Book Reviews.

Diet in Health and Disease. By Julius Friedenwald, M.D., and John Ruhrah, M.D. Second edition, thoroughly revised and enlarged. Philadelphia and London. 1906.

The first edition of this book appeared in 1905 and was reviewed in these columns.

While there are no radical changes in this second edition numerous minor revisions and additions remove some of the previous criticisms.

In the chapter on Chemistry and Physiology of Digestion reference has been made to Professor Chittenden's Experiment on Physiological Economy in Nutrition.

Additions have been made in the chapter devoted to Recipes.

A new list of diets arranged under the headings of the more common diseases has been inserted at the end of the book.

The concise manner in which the entire subject of Foods and Diet is treated recommends it as a book for ready reference.

Abdominal Operations. By B. G. A. Moynihan, M.S. (London), F.R.C.S. Leeds. Second edition, thoroughly revised. Philadelphia and London: W. B. Saunders Company. 1906.

The first edition of Moynihan's book was exhausted in a few months and this second edition needs no apology. Certainly the book is one which should be familiar to every surgeon. It is the work of a master; a skilled technician, personally and abundantly familiar with the problems of which he treats, and he writes in a fashion which compels attention. He is interesting, pointed and practical, but not diffuse. Generously and almost unnecessarily he gives credit where credit is due. Perhaps one misses the abundance of quoted cases and the general philosophizing, which so often have made readable, and added charm to, elaborate surgical treatises, but Moynihan's purpose is directly and immediately to tell his story and to teach his lessons. In this he succeeds admirably.

As the author says, he concerns himself exclusively with the surgery of organs common to the two sexes and embraced entirely by the peritoneum. He omits, therefore, all consideration of genito-urinary and gynecological surgery. The book is divided into five sections and is fairly well illustrated. One regrets the absence of an index to the illustrations. Section I comprises 9 chapters and deals with such general considerations as bacteriology, methods of operating, complications and sequels, peritonitis, abscess and visceral ptosis. It would be futile here, as elsewhere in this short review, to criticize in detail Moynihan's dealing with these subjects. He appeals to every progressive surgeon. One notes, however, that in dealing with the treatment of diffuse peritonitis he fails to describe J. B. Murphy's important and useful "seeping" method. To this reviewer he seems to lay too little stress also on the value of pelvic fixation and abdominal support in the treatment of visceral ptosis. Sections II and IV, made up of 19 chapters, comprise elaborate dissertations on those surgical operations for which Moynihan is most famous in this country,—operations on the stomach, liver and bile passages. Those of us who have read his previous books, compiled in association with Mayo-Robson, will recognize the familiar note of his former writings. Probably no other book to-day sums up so completely the surgical treatment of gastric and hepatic disease as this latest work of Moynihan. Section III, including 13 chapters, treats of operations upon the intestines, and in this field the author finds scope for expressions of conviction, which many American readers will learn for the first time. He gives us in Chapter XX a full and elaborate résumé of Monk's well-known views on intestinal localization, reproducing that writer's admirable illustrations; he devotes Chapter XXI to the subject of sutures, and then in subsequent chapters goes on with an excellent summary of the more important operations upon the intestines, — enterostomy, colostomy, anastomosis, resections, operations for rupture and obstruction, for embolism and fecal fistula. Chapter XXX contains a readable discourse on the treatment of appendicitis, while the following two chapters deal with typhoid perforation and intestinal occlusion. Section V, comprising 8 chapters, treats of diseases of the pancreas and spleen. The opinions there expressed and the conclusions drawn are in no wise remarkable, but the summary of knowledge given is highly satisfactory.

Although the reviewer of Moynihan's book finds in it no startling assertions or striking novel propositions, he is constantly impressed with the personal note struck by the writer. There is no flavor of scholiast or pedagogue. Moynihan writes as a practical surgeon addressing himself to practical surgeons, with the result that he has produced a book altogether acceptable in the reading, instructive of present accomplishments and suggestive of future brilliant possibilities in the great field of abdominal surgery.

The Practical Medicine Series. Under the general editorial charge of GUSTAVUS P. HEAD, M.D. Volume ix, Anatomy, Physiology, Pathology, Dictionary. Edited by W. A. EVANS, M.D., ADOLPH GEHRMANN, M. D., and WILLIAM HEELY M.D. Series 1906. Chicago: The Year Book Publishers. 1906.

This is a good work for practitioners who wish to keep in touch with recent advances in physiology and pathology. Nearly all the articles abstracted deal with subjects of interest and importance to clinicians. The reviews are well written and the salient points clearly presented. Only seven pages are devoted to anatomy. The section on physiology occupies 25 pages, nearly 200 pages deal with pathological and bacteriological topics. At the end of the volume is a list of new medical words with definitions.

Surgical Diseases of the Chest. BY CARL BECK, M.D., Professor of Surgery in the New York Post-Graduate Medical School and Hospital. Visiting Surgeon to the St. Mark's Hospital and the German Poliklinik, etc. With 16 colored and 162 other illustrations. Philadelphia: P. Blakiston's Son & Co. 1907.

Beck's fairly comprehensive monograph, profusely illustrated and well presented by his publishers, is valued at $5 a copy. We fancy this fact will limit its sale. After a laborious search of the literature and what appears to have been an honest, painstaking study of his topic, the author has produced a manuscript which would doubtless have made an admirable showing in a System of Surgery or small book, but the elaborate and ambitious presentation by the publishers may deceive the unwary into believing that they are purchasing an exhaustive volume. It is obvious, however, that the author has done his work frankly and conscientiously. He points out in his preface that surgery of the chest is a much neglected field compared with the surgery of other cavities of the body, and proposes modestly to make good the lack.

The book contains six chapters, on the anatomy of the thoracic wall and the diaphragm; on the surgery of the thoracic wall; on intrathoracic diseases; on the value of the Röntgen method in thoracic surgery; on subphrenic abscess, and on diseases of the breast. There is an admirable bibliography and a partial index.

We have read through this book with some care and have gleaned from it a good deal of suggestive information, particularly on tumors of the thoracic wall and on the surgery of the heart and lungs; but we find no striking new contributions to the very interesting subject with which the author deals. A detailed criticism of the book seems needless, though one cannot but regret a somewhat faulty perspective in the general arrangement and frequent obscurity in phrasing.

We commend the book to the general surgeon, for it certainly sums up, in convenient form, our present knowledge of a difficult and little understood subject.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 29, 1907

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

HEMORRHAGIC INFARCT OF THE INTESTINE.

HEMORRHAGIC infarct of the intestine is a lesion which is produced by the obliteration of a mesenteric artery or vein. An infarct of venous origin is usually due to a thrombophlebitis of the mesaraic veins. The blood stagnates in the intestinal portion of the vein, and produces a congestion with the progressively increasing tension, due to the continual afflux of arterial blood. The origin is varied.

These venous thromboses may be secondary, and represent the result of the extension of an adhesive pylephlebitis primarily seated in the veins of the mesentery. When the lesion is primary it appears in the intestinal veins following a general infection, or even from a purely intestinal infection. An infarct thus produced rarely becomes localized to the large intestine by thrombosis of the inferior mesenteric vein. Usually, however, the small intestine is the seat of the lesion, the thrombosis involving one or several branches of the superior mesenteric vein. One will find a sanguineous infiltration involving a segment of the mesentery, varying from one half to one meter in length, with a very intense congestion of the capillary vessels and thrombosis of the veins. The loop of intestine becomes necrosed and contains hemorrhagic products. A sero-sanguineous ascites arises in all cases, although small in amount; the quantity of fluid never exceeds 1,000 cc.

The clinical evolution of intestinal infarct presents much similarity with that of intestinal obstruction. The patient is suddenly seized, in the midst of flourishing health, with violent abdominal pain and vomiting, which, in the first place, is merely alimentary, but which is not long in becoming bilious. The pains rapidly become

diffused, extending towards the kidneys and lumbar region, and their acuity remains just as severe up to the time of death. From the very onset a very abundant diarrhea makes its appearance; the stools are liquid and yellowish in color and are constantly voided. This diarrhea is of short duration, and in less than twenty-four hours all movements cease and the clinical picture changes to that of intestinal occlusion accompanied with fecaloid vomiting. In other cases the diarrhea persists and takes on a bloody aspect; this enterorrhagia is a most important and almost pathognomonic sign when it appears, accompanied by the abdominal pain and vomiting.

Upon examination in the early progress of the affection, one may find a tympanitic area localized over the coil of gut involved, but later on by palpation a soft, elongated, rounded tumor may be felt, movable under the exploring hand and easily palpable, this representing the diseased gut. At the time that the symptoms of occlusion appear, the abdomen becomes generally distended, and there is slight dullness in the iliac regions, due to the hemorrhagic ascites.

In other words there are two distinct periods in this affection; in the beginning there is pain and diarrhea and later on occlusion. Death is the final outcome when the patient is not radically treated and occurs either in coma or collapse.

The diagnosis is easy, for it is sufficient to recall hemorrhagic infarct with its evolution divided into two stages, which are practically characteristic, and when once the diagnosis is made, treatment should be undertaken at once. This is, laparotomy with resection of the diseased intestinal coil, followed by end-to-end anastomosis. The two cut ends of the gut may also be stitched into the wound, thus creating an artificial anus. At the present time, the affection being most infrequent, few cases have been recorded, but by early operation two complete cures up to this time have been obtained.

REPORT OF THE IMPERIAL CANCER RESEARCH FUND.

The fourth and fifth annual reports of the Imperial Cancer Research Fund, which is under the direction of the Royal College of Physicians of London and the Royal College of Surgeons of England, are in our hands. The earlier reports gave a detailed description of contemplated investigations and were taken up essentially with methods of organization and of prospective work. In the third report certain definite results were given, but the general result of the three years' investigation has led to a certain alteration in the plan of work, which is shown in these last reports. Although perhaps not so apparent, an increasing amount of work is being done, concentrated particularly on the nature of cancer and on attempts to control the disease artificially. The staff of workers in the laboratory has been increased, and many papers have been published representing the discovery of a considerable number of new facts. The time, however, is thought not yet to be ripe for the publication of a scientific report, which would be the third from this laboratory.

The general results of the past year, largely obtained through animal experimentation, controlled by comparative biological and statistic investigations, have thrown light on the nature of the local and constitutional conditions associated with the origin of cancer, and it has also been possible to form more definite conceptions of the nature of the change responsible for the rapid multiplication of cancer cells. Some interesting statistical facts have been secured regarding the relative frequency of cancer in different parts of the body, occurring in particular geographical regions. Recognizing the fact that cancer may occur in all vertebrate animals, it has been concluded that the search for a common external agency is futile, but that the search for a common intracellular change will presumably lead to more definite results. There is no evidence justifying the communicability of the disease from person to person, and it therefore follows that individual and family liability should receive increased attention. Death from cancer is a menace of much importance and, possibly, though this is not definitely established, of increasing significance. A recent statistical estimate in England shows that after passing the age of thirty-five the chance that a man will die of cancer is one in twelve and a woman one in eight. Such statistics are always of interest, though much remains to be done on this side of the question before the real significance of these figures may be properly estimated.

The experimental investigations have concerned themselves largely with inoculation of cancer and with minute study of the development of the cancer cell and the conditions under which this is possible. One conclusion of significance is that no satisfactory evidence of the existence of substances in the serum of affected animals exists which is directly harmful to the cancer cell. Alleged cures of cancer have been investigated

with the not unexpected result that no curative value has been found in any of them. The much advertised trypsin cure has proved wholly inefficacious on careful experimentation and has been found incapable of curing mice of inoculated cancer or of influencing the progressive growth of tumors. The complete surgical removal of the new growth remains the only effective method of cure.

SIXTH INTERNATIONAL DERMATOLOGICAL CONGRESS.

The sixth International Dermatological Congress, which is to be held at the New York Academy of Medicine from Sept. 9 to 14, under the presidency of Dr. J. C. White, of Boston, bids fair to be the most important meeting on cutaneous diseases which this country has seen. It is a sign of progress that papers may be presented in five languages, either English, French, German, Spanish or Italian, and may be discussed in the language most familiar to the speaker. If we fail in the attainment of a universal language, which on the whole seems probable, it will not be many years before men of intellect will be able to understand and possibly to discuss papers delivered in the leading foreign languages. Such a meeting as this of the Dermatological Congress is likely to do much toward bringing about such a result.

The program contains many subjects of vital interest to medical science and to medical practice. The field of dermatology has been rather unexpectedly broadened during the last few years; in the first place through the revelations of bacteriology, and in the second, through the increasing knowledge of parasitic diseases. We notice among other papers of special interest one by Dr. W. R. Brinckerhoff, on the "Reaction of the Rat to Inoculation with Leprous Tissue." Although it is not to be supposed that Dr. Brinckerhoff's researches have yet gone very deeply into the etiology of leprosy, owing to the short time he has been engaged in this work, the preliminary results of his investigations will be awaited with interest. It is announced that Dr. E. E. Tyzzer, of Boston, will speak on the Pathology of the Brown-Tail Moth Dermatitis and Dr. H. P. Towle on Hysterical Skin Gangrene, a subject which has long excited an active and at times heated discussion. The opsonic methods as applied to skin diseases are to be discussed by Arthur Whitfield, of London, and the general topic of syphilis, presented by Professor Neisser, of Breslau, will undoubtedly be of much interest. In general the meeting promises to be a most notable one, and we may expect that at least a temporary ultimatum will be given on many subjects related to cutaneous medicine.

DEATHS BY LIGHTNING.

That the somewhat widespread fear of thunderstorms is in a measure justified is shown by recent data collected by the Weather Bureau. According to this report, it is stated that about 800 people are killed in the United States each year by lightning, or approximately one to each 100,000 of the population. The regions which are most dangerous in this respect constitute a statistical study not without interest. It appears that the greater part of Florida, the lower edge of Georgia and a corner of Alabama experience the greatest number of thunderstorms yearly, about forty-five. Slightly further north the number of storms decreases, although they are frequent throughout the Southern States and also in the more southern of the Central States. From the Virginia capes to Connecticut an average of twenty-five thunderstorms occur yearly. Boston has twenty each year. From the New England States toward the west the frequency of storms decreases until on the Pacific Slope there are practically none. The regions of greatest danger, however, do not correspond with the frequency of storms. Southern Vermont, Massachusetts, Rhode Island, Connecticut, New York and a number of states west and south give a record of five deaths to each 10,000 square miles. The statistics furthermore show that four times as many persons of outdoor pursuit as of indoor occupations are struck. Of those struck one in every three persons survives, and this proportion might be greater if immediate treatment were at hand. Finally, more than half the persons killed by lightning are those who have taken refuge under trees. The foregoing figures certainly show that lightning as a cause of death is not negligible, and also that during violent thunderstorms ordinary precautions against being struck are justifiable and should not be regarded as an excess of timidity.

MEDICAL NOTES.

A Hospital for Automobile Victims. — It is stated that the family of the late Thomas E. Stillman, of New York, has given to the town of Lisieux, France, an addition to its hospital where accidents, especially those resulting from automobiles, are to be treated. The gift is made in

memory of Mr. Stillman who died in the hospital a year ago from injuries sustained in an automobile accident. The addition to the hospital has been formally accepted by the mayor, and the names of the donors will be inscribed on the tablet reserved for benefactors of the city.

A National Sanitation Board for Cuba. — It is reported that a National Department of Sanitation is to become effective in Cuba, the *personnel* of the department consisting of one chief and a board of five members holding office for four years. This board will have complete control of sanitary matters in Cuba, and it is expected through its means to prevent future outbreaks of yellow fever, as well as to regulate other matters of public health.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Aug. 28, 1907, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria, 34, scarlatina 26, typhoid fever 24, measles 12, tuberculosis 42, smallpox 1, leprosy 1.

The death-rate of the reported deaths for the week ending Aug. 28, 1907, was 19.60.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, Aug. 24, 1907, was 243, against 227 the corresponding week of last year, showing an increase of 16 deaths and making the death-rate for the week 20.79. Of this number 135 were males and 108 were females; 241 were white and 2 colored; 166 were born in the United States, 75 in foreign countries and 2 unknown; 47 were of American parentage, 168 of foreign parentage and 28 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 35 cases and 1 death; scarlatina, 23 cases and 0 deaths; typhoid fever, 19 cases and 2 deaths; measles, 14 cases and 1 death; tuberculosis, 57 cases and 28 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 16, whooping cough 2, heart disease 16, bronchitis 3 and marasmus 11. There were 19 deaths from violent causes. The number of children who died under one year was 81; the number under five years, 100. The number of persons who died over sixty years of age was 45. The deaths in public institutions were 97.

There were 2 cases and 2 deaths reported from cerebrospinal meningitis during the week.

A Case of Leprosy. — It is stated that a man forty-five years of age, a resident of Lynn, Mass., is suffering from leprosy and that he will be taken to the Leper Colony on Penikese Island. The patient is a Russian by birth and has been in this country several years. Although he has been under observation for some time, the disease has only recently been diagnosticated as leprosy.

Public Health in Massachusetts. — In the course of a recent speech at Provincetown, Mass., President Roosevelt paid the following tribute to Massachusetts:

"I also hope that there will be legislation increasing the power of the National Government to deal with certain matters concerning the health of our people everywhere; the Federal authorities, for instance, should join with all the state authorities in warring against the dreadful scourge of tuberculosis. Your own state government, here in Massachusetts, deserves high praise for the action it has taken in these public health matters during the last few years; and in this as in some other matters, I hope to see the National Government stand abreast of the foremost state governments."

NEW YORK.

Arrest for Neglect of Medical Aid. — Peter Paterson of Tottenville, Bourough of Richmond, has been arrested and committed to jail in default of $2,000 bail, on a charge of criminal negligence in not accepting medical aid for his infant daughter, fifteen months old, who died on Aug. 19 from whooping-cough and summer diarrhea. Both the parents of the child belonged to a sect known as the Christian Alliance, which like the Eddyite cult, rejects medical attendance, and at the coroner's inquest on the case it developed that when they found it was seriously ill they sent for a regular physician, simply that a death certificate might be obtained in case it should not survive. His prescriptions were never filled and prayer alone was relied on for relief of the illness.

Death of Dr. Miles Henry Nash. — Dr. Miles Henry Nash, of New York, died recently at Ridgefield Park, N. J. He was born in Norfolk, Va., in 1833, and was graduated from Jefferson Medical College, Philadelphia, in 1855. He began practice with his father in Tallahassee, Fla., and later served throughout the Civil War as a surgeon in the Confederate Army. For a considerate time he was in charge of the Llewellen Hospital. At the close of the war he practised for a short period in Georgia and then removed to New York, where for eight years he was assistant to Dr. J. Marion Syms, the eminent gynecolo-

gist. For twenty-six years he was connected with the Demilt Dispensary, first as an attending physician, and from 1888 as house physician. A few months ago, when his health began to fail, he was made physician emeritus. His faithfulness and kindly disposition endeared him to the large medical staff of this great institution and to thousands of patients.

Epidemic of Typhoid Fever at Trenton Insane Hospital. — The State Sewage Commission of New Jersey has just made a report on the epidemic of typhoid fever at the hospital for the insane at Trenton which states that their investigation showed that the outbreak was due to a leak in the city's sewers, which seeped into a spring used for drinking purpose. A report made at the same time by the medical committee of the hospital managers states that since April 8, 1907, there have been 103 cases of typhoid in the institution, as follows: Number of cases in April, 4; in May, 11; in June, 15; in July, 62; Aug. 1 to Aug. 15, 11. Of these patients 18 were individuals employed about the hospital grounds, and the remaining 85, patients and attendants. There have been 18 deaths from the disease, 2 of which occurred in patients treated outside the institution. On Aug. 15 there were 41 patients still under treatment. On only 4 of these was the temperature over 99°, most of the remaining ones being in advanced convalescence.

Bequests. — Frederick F. Ayer, of New York, has presented, through Dr. Moses G. Parker, the sum of $100,000 to the Ayer Home for Young Women and Children at Lowell, Mass., for the purpose of enlarging the work of the institution.

Among the charitable bequests in the will of the late Cortlandt Parker, of Newark, for many years the leading member of the bar in New Jersey, is $3,000 to St. Barnabas' Hospital in Newark.

Obituary.

CHARLES FOLLEN FOLSOM, M.D.

Dr. Charles F. Folsom, of Boston, died in New York at the Roosevelt Hospital, Tuesday, Aug. 20, 1907. He was born in Haverhill, Mass., April 3, 1842; his father was a clergyman, Nathaniel Smith Folsom, D.D. Dr. Folsom was graduated from Harvard College in 1862, and took, in addition to his bachelor's degree, the further degree of Master of Arts. He later entered the Harvard Medical School, receiving his degree in medicine in 1870. The long interval between his graduation in the academic department and the medical school is accounted for by the fact that he passed some time in South Carolina as a representative of the Freedman's Bureau. During his stay in the South he contracted malarial fever which necessitated a long sea voyage and still further delayed the prosecution of his professional studies. As a part of his preliminary medical training, he served as a medical house officer at the Boston City Hospital, and at once thereafter entered upon the practice of his profession in Boston.

From that time forward Dr. Folsom held many places of trust and responsibility and steadily advanced to a high professional standing. One of his interests, which he maintained to the end of his life, was the somewhat neglected study of mental disease. In pursuance of this interest, he served for a time at the McLean Asylum, connected with the Massachusetts General Hospital. He was also a lecturer on mental diseases at the Harvard Medical School, from 1879 to 1882, and from 1882 to 1885 an assistant professor in the same subject. Previous to this he had also lectured on matters connected with hygiene, and in the years 1877 and 1878 had the title of lecturer in that subject. His interest in hygiene began soon after his entrance upon the practice of medicine. In 1874 he succeeded Dr. George Derby as secretary of the Massachusetts State Board of Health and maintained his connection with the board for eight years. He was also a member of the first Metropolitan Sewerage Commission, and was one of the commissioners appointed by the National Board of Health to inspect Memphis, Tenn., after the serious outbreak of yellow fever there. He subsequently succeeded Dr. H. I. Bowditch as a member of that short-lived board. In 1879 he was made secretary of the Massachusetts Board of Lunacy and Charity, a position which he held for two years. He was for many years on the Staff of the Boston City Hospital as a visiting physician, but resigned long before his usefulness to the institution began to wane. He was appointed by Governor Wolcott a member of the commission to inspect State Charity Institutions, of which Prof. Davis R. Dewey was also a member and of which Mr. W. F. Wharton was chairman. Dr. Folsom served as an overseer of Harvard University from 1891 to 1903, inclusive, and during this long term of service proved a most useful member of the board. More recently he held the position of president of the Harvard Medical School Alumni Association; in fact, this was one of the last honors to be conferred upon him. Dr. Folsom's society affiliations were large. He was a fellow of the American Academy of Arts and Sciences, honorary member of the Association of American Physicians, a member of the American Medical Association, a fellow of The Massachusetts Medical Society, a member of the Boston Society for Medical Improvement, the Boston Society of Medical Sciences, the Boston Society of Psychiatry and Neurology, a member of the Boston Statistical Society, of the National Geographical Society, and a trustee of the Danvers Asylum during its early years. He was also connected

as physician at one time with the Massachusetts Infant Asylum and with the Carney Hospital. He wrote on many subjects connected with hygiene, public health, mental disease and general medicine, both in reports and journals.

The mere mention of the positions which Dr. Folsom held, the duties of which were always most conscientiously and serviceably discharged, indicated exact industry, rare attainment and unusual versatility. He achieved high standing and wide reputation in hygiene, in state medicine, in psychiatry and neurology, and since 1881 took a foremost place as a practitioner and consultant in internal medicine. He was a very competent diagnostician and a resourceful therapeutist with confidence in the action of drugs. His patience and kindness to the sick and the sorrowful who sought his care and counsel were beyond all praise. As a writer he was clear, concise, convincing. He was for many years a valued coadjutor on this JOURNAL. Dr. Folsom went to Europe with his wife early last June and returned unexpectedly, suffering from a malignant endocarditis, from the effects of which he died. He will be greatly missed by many people. The state, the community and his profession are all the poorer for his death and that at an age when continued service might still have been expected from him.

6. HALL, J. N. *The Need of Earlier Diagnosis.*
7. KELSEY, C. B. *Two Unusual Cases of Rectal Hemorrhage.*

1. Bettmann finds that new impetus has been given to researches as to the physiology of the digestive system. As to gastric peristalsis, emotions inhibit it and handling the intestines does the same. Operations close the pylorus for six hours. The impulse for the closure of the pylorus is due to the reaction of acid chyme. We have recent additions to the knowledge of the movements of the intestine. There is an oscillatory movement that breaks up the food masses, but does not propel it forward. By antiperistalsis the bowel contents are churned about in the cecum until most of the liquid is removed. The small intestine is inhibited by vagus stimulation, and excited by the splanchnics. True peristaltic waves are caused by stimulation of Auerbach's plexus. Knowledge of the chemistry of digestion has been much increased. Pepsin is secreted before food enters the stomach, and pancreatic juice when the chyme enters the duodenum. The excitor of pancreatic secretion is secretin, produced by the duodenal mucosa when stimulated by HCl. The upper small intestine secretes, while the lower absorbs. Gastric digestion is relatively unimportant. The study of the feces gives valuable information. Mucus means inflammation, if visible in the colon. Purulent mucus means ulceration. Connective tissue remains in the stool means impaired gastric digestion. Intestinal disorders are hepatogenic, pancreatogenic, or essential intestinal. Too good a digestion, leaving little residue, may cause constipation. The intestinal bacteria offer a new field for investigation. As old age approaches intestinal putrefaction is easier. There are the indolic type, the saccharobutyric and the combined types. Cholecystitis is practically always due to infection.

NEW YORK MEDICAL JOURNAL.
AUGUST 3, 1907.

1. *PEABODY, G. L. *A Case of Carcinomatous Metastases in Unusual Sites.*
2. *JACOBY, G. W. *Intradural Resection of the Posterior Roots of a Number of Spinal Nerves for the Relief of Intractable Pain.*
3. BRAV, H. A. *Aetiology and Treatment of Pruritus Ani.*

7. WIGHT, J. S. *Post-operative Treatment of Malignant Disease of the Buccal Cavity.*

1. Peabody's case is unusual in that the metastases from a cancer of the breast seemed to show a predilection for the central nervous system, occurring especially in the meninges, the spinal cord and the peripheral nerves.

2. Jacoby advocates a more general use of the intradural resection of posterior spinal nerve roots for the relief of intractable pain. This operation has commonly been regarded as one in which the danger is out of proportion to the results to be hoped for. This opinion, however, is based only upon three cases, in one of which a moderate Brown-Séquard paralysis occurred from clot formation, and in two of which death followed the operation, probably not from the operation alone. Jacoby believes that the danger of this operation is not greater than that involved in simple laminectomy. He cites 15 cases (one original). In only 13 of these is the late result given. In 8 of the 13 the relief proved permanent and complete; in the remaining 5 there was amelioration of the pain, but only incomplete relief. In the cases of incomplete relief it is believed that the number of nerve roots resected was insufficient.

4. Vedder reports the results of studies of the blood in dengue made during an epidemic at an army post in the Philippines. He finds, as other authors have done, that the red count is not notably changed but that leukopenia is constant throughout the disease. By differential counts it is shown that the polymorphonuclear leukocytes are early greatly diminished, and that a corresponding increase occurs in the small lymphocytes. There is a more moderate increase in the large lymphocytes, and a slight one in the eosinophiles. These features of the differential count are suggested as points of some value in distinguishing dengue from malaria and from yellow fever.

2. Gottheil's article is an enthusiastic description of the advantages which he maintains are to be gained by the use of intramuscular injections of insoluble salts of mercury, chiefly the salicylate, in the treatment of syphilis. The results are held to be much more rapid and more efficacious, both in the cure of the disease and in the prevention of relapses. As a matter of convenience to the patient the method is further said to be preferable to that of medication by mouth or by inunctions, since the weekly or bi-weekly injections, if properly given, are almost painless and without danger. One precaution, however, is to be observed, — the needle, disconnected from the syringe, should be watched for a few seconds after it is inserted to make sure that it has not entered a vein, an occurrence met in perhaps one out of 25 injections. Toxic effects have been rare. In the discussion following this paper the general feeling seemed to be adverse to the injection of insoluble mercurials on the ground that the absorption was uncertain and could not be controlled.

3. Whitehouse believes that we have in liquid air a dermatologic remedy of real worth, at least in a limited field. He gives its physical properties and the facts so far as known as to its bactericidal value, which seems to be practically *nil*. We must look, therefore, to changes induced by it in cellular metabolism for its therapeutic effects, and he states that it relieves pain in pathologic conditions, lessens discharge and odor and tendency to hemorrhage. Mild applications favor healthy granulation, while stronger ones destroy exuberant growth. It has little reactionary effect on scar tissue, and, therefore, he believes that it has a diagnostic value on epithelioma. The conditions in which he finds it of value are pigmentary, hairy and vascular nevi, angiomata, lymphangioma circumscriptum, lupus erythematosus, lupus vulgaris and epitheliomata (unaccompanied by lymph-gland invasion). It should be applied on a swab, which can be adapted to any form desired, and the elements governing the effects produced are: (1) the degree of saturation of the swab; (2) the accuracy of contact; (3) the amount of pressure exerted, and (4) the duration of the exposure. As a rule, the slower the method the better the result. Special directions are given as to the treatment of the various conditions and a number of cases are reported. He thinks that in a certain class of epitheliomata it is a distinct power for good.

8. Schmieden calls attention to Bier's method of treating pseudarthrosis and retarded callus formation by injections of human venous blood between the separated fragments of bone. It is based on the theory that the formation of callus in fracture is due to the inflammatory reaction caused by the hemorrhage attending the fracture, and this inflammatory reaction failing, we can re-excite it by making, so to speak, an artificial hemorrhage. In Bier's clinic, the technic is as follows: The site of the "false joint" as well as the arm from which the blood is taken are rendered aseptic. By the use of a light constricting band the veins are made prominent and then one of the largest vessels is punctured or incised and 30 or 40 cc. of blood are drawn into the syringe. The syringe must be large and its needle sufficiently strong in order that the blood can be readily forced through it. It must be strong also because much force is needed to inject into the hard scar tissue. The blood must be forced, not only between the fractured ends, but also around them in places where, from periosteal and paraosteal tissue, callus may be formed. It is important also that the blood be injected immediately after its removal, using the same syringe into which it has been drawn to prevent coagulation in the syringe. Blood containing its fibrin gives better results than defibrinated blood. From 20 to 40 cc., according to the size of the bones, is injected, the operation being repeated every ten days. In most cases there is a visible reaction and after its subsidence a tumor remains that becomes callus. Sometimes one or two injections suffice, in other cases five or six may be needed. The more recent the fracture the greater the success, hence the best results are obtained in cases of retarded callus formation. In some old cases of pseudarthrosis the method fails, but the same is true of all other methods. In a large number of injections made in this way he has never seen any harmful effects. He has often injected blood taken from another healthy subject and has found it more effective. The facts support the conclusion that the extravasation of blood is the natural irritant which excites callus formation. The technic is simple, and the method is recommended with the hope that the results obtained in Bier's clinic will be substantiated by the experience of others.

10. Kyle believes that hay-fever can be traced, in a large proportion of cases, to abnormalities in the nasal secretion and the saliva. He has done much work in the investigation of the saliva and mentions a number of conditions which he regards as of clinical importance. The reaction may be excessively acid or excessively alkaline. There may be an excess of ammonia compounds or of sulphocyanides. In treatment of hay-fever he maintains that we should be guided by the results of such examinations. By means of the internal use of the citrate, lactate or benzoate of soda, the dilute mineral acids, the salicylates or sodium chloride, he has been able to relieve 60% of his cases without local treatment.

11. Harris discusses the so-called slow fever which occurs during the summer months in southern Georgia. It has been variously regarded as a form of malaria, as a form of typhoid, and as a distinct disease in itself. The clinical symptoms are not described at length, but the essential feature is the continued fever with absence of the usual positive evidences of typhoid. The author has studied 45 cases of the disease. In 24 of these the spleen was enlarged. Blood smears made in all cases failed to show the presence of malarial organisms. Blood cultures from 12 cases yielded typhoid bacilli in 6 cases and paratyphoid in one. Agglutination tests were positive in but 12 of the 45. Two cases were fatal but no autopsies could be obtained. In the discussion which followed the reading of this paper it was generally agreed that the disease must be a mild atypical form of typhoid.

13. Adler calls attention to the indicator discovered by Dr. R. L. Emerson, of Boston, called "carminogen." Solutions of this reagent in contrast to those of Günzburg's reagent, are permanent. Test papers, made by saturating filter paper with such solutions, are also permanent if kept from the air. As an indication for the free mineral acids carminogen is fully as delicate as Günzburg's reagent.

1–7. Halsted reports 32.3% of cures of cancer of the breast based on a total of 232 cases The immediate operative mortality was 1.7%. The statistics of the Massachusetts General Hospital have been already abstracted. (See BOST. MED. AND SURG. JOUR., Aug. 15, p. 237.) Of 98 cases traced, Ochsner reports 34 which have lived beyond the three-year period following operation for breast cancer. Of 71 cases traced by Jacobson which were operated more than three years ago, 35 are still living; 33 died of metastases, and 3 within a year after operation of other diseases. Cabot has operated on 42 private cases of breast cancer up to 1904. Nine are free from recurrence (21.4%); 5, though living, have recurrence.

10. Gwyer reports marked benefit in the treatment of inoperable carcinoma by extract of the calf's thymus gland. It has been found to produce the following results: (1) diminution or elimination of pain; (2) diminution of the size of the growth; (3) "Its use is followed by better digestion, by more regular action of the bowels, and improvement of the general condition, as evidenced by a clearer skin and eyes, greater energy and a general sense of health and well being." Gwyer still advises operation in all operable cases, and also in so-called inoperable cases for the removal of as much diseased tissue as possible, so there will be a minimum to be absorbed and eliminated.

11. Syms, from a review of the literature on peritoneal tuberculosis during the past ten years, emphasizes the following points: (1) operations should not be undertaken during the first year of infancy; (2) surgery offers but little hope in the adhesive variety of the disease; (3) the serous variety offers the best prognosis under the various forms of treatment, and the surgical treatment of this variety offers the best results obtainable in this disease; (4) the operation should have as its foundation the removal of the original focus of the disease, as tubercular Fallopian tubes, appendix or mesenteric glands; (5) laparotomy should not be performed when the peritoneal trouble is only one phase of a more or less general tuberculosis. [W. C. Q.]

THE LANCET.

JULY 27, 1907.

1. SIMPSON, W. J. R. *The Croonian Lectures on Plague. No. IV.*
2. HEWITT, F. W. *General Surgical Anesthesia Lecture. No. II.*
3. *BUCHANAN, R. M. *The Carriage of Infection by Flies.*
4. *ROSS, R., SALVIN-MOORE, J. E., and WALKER, C. E. *A New Microscopical Diagnostic Method and Some Simple Methods for Staining Liquid Blood.*

6. PAVY, F. W. *A Study of the Conditions producing the Anomalous Reaction not Infrequently met with in Testing Urine for Sugar with Fehling's Solution.*
7. WILLIAMSON, T. D. *A Case of Cerebro-Spinal Meningitis during Pregnancy.*
8. *NIERENSTEIN, A. *The Treatment of Trypanosomiasis.*
9. EDE, F. C. *Cerebral Hyperemia as a Factor in the Therapeutic Action of Lumbar Puncture (Illustrated by a Case of Tetany).*

3. Buchanan presents experiments on the carriage of infection by flies in swine fever, staphylococcal abscess, pulmonary tuberculosis and anthrax. He shows that flies alighting on any substance containing pathogenic organisms are capable of carrying these organisms in large numbers on their feet, and depositing them on surface after surface with which they come in contact.

4. Ross and Salvin-Moore describe certain granular elements in normal red blood corpuscles supposed to be nuclear remains. These can be found with appropriate staining methods in normal blood and in one case of malarial anemia they were present up to 11%. Three methods of staining liquid blood are described.

5. Rundle and others give the details of a case of cerebrospinal meningitis successfully treated with a vaccine made from an organism isolated from the patient's blood. They are confident of good results in other cases.

8. Nierenstein discusses the treatment of trypanosomiasis by arsenic compounds, by dye-stuffs (malachite green, fuchsin, etc.) and by atoxyl. He gives the preference to atoxyl, to be followed by mercury and fuchsin. [J. B. H.]

6. HEWLETT, R. T., and DE KORTÉ, W. E. *On the Etiology and Pathological Histology of Beri-beri.*
7. SYMES, J. O. *Arthritis and Erythema Nodosum.*

2. The most striking feature of the eye symptoms in meningitis is the great variety shown — squint, retraction of the lids, changes in the size and reaction of the pupils, etc. — in the same patient from day to day. Conjunctive hemorrhages, which do not occur at the onset of other acute illnesses, may be useful in diagnosis. The presence of conjunctivitis is also an early symptom, and may help to distinguish this from other forms of meningitis. The absence of ocular symptoms does not justify a favorable prognosis. [J. B. H.]

17. SIKES, A. W. *Gouty Glycosuria.*
18. WILLIAMSON, R. T. *On the Action of Certain Drugs in the Treatment of Diabetes Mellitus and Chronic Glycosuria.*
19. PARSONS, A. R. *The Treatment of Diabetes Mellitus by Drugs.*
20. DAWSON, B. *Glycosuria and Life Insurance.*

1. Halliburton summarizes the latest news on the physiology of the liver and the pancreas in relation to glycosuria and diabetes, and discusses in detail the various animal experiments from which these facts have been deduced.

2. Bradford presents cases and discusses the various lesions of the pancreas which do and do not cause diabetes. Experimental results certainly associate glycosuria with the loss of an internal pancreatic secretion, and post-mortem evidence tends to show extensive degeneration of the islets of Langerhans in diabetes.

4. Labbé summarizes the treatment of diabetes by diet, gives his own special methods, and considers those recommended by others.

6. The treatment of diabetes in Carlsbad can be divided

into five parts: (1) internal use of the waters; (2) the diet; (3) baths; (4) the use of all those different therapeutic methods and proceedings called "physiologic therapy"; and (5) pharmaceutical treatment. These Kraus takes up in detail. He urges physicians to send cases for treatment in the early stages when they are yet in a position to benefit by a stay at Carlsbad.

12. Wallace strongly advises amputation of all cases of diabetic gangrene, not only for surgical reasons but because the progress of the disease itself is sometimes checked, and often sugar disappears from the urine, temporarily at least.

13. In children the onset of diabetes is more sudden, the course more rapid and the termination almost invariably fatal. There appears to be greater freedom from associated diseases, especially pulmonary complications. During twenty-two years at St. Bartholomew's Hospital out of 506 diabetics 5.4% were under sixteen years. Heredity seems to be a strong factor in the etiology of this condition. Acute illnesses may be predisposing factors. Skin affections are very common. As regards diet in children a strict carbohydrate-free diet only rarely can be adopted.

15. Acetonuria is the result of increased metabolism of fat. This will occur in any starving tissue, but it is particularly apt to occur if oxidation is deficient. Deprivation or non-utilization of carbohydrate food causes both starvation and deficient oxidation. Acetonuria is often seen in diabetes, recurrent vomiting, pernicious vomiting of pregnancy, in certain gastro-intestinal disorders, and associated with broncho-pneumonia as well as a result of delayed chloroform poisoning. The treatment depends on the cause but consists largely in diminishing the fat, increasing the carbohydrates, and neutralizing the acids already formed by soda bicarbonate.

MÜNCHENER MEDIZINISCHE WOCHENSCHRIFT, No. 24. JUNE 11, 1907.

11. IPSEN, W. *Silvery Discoloration of the Hair.*
12. KRAFT, E. *The Demonstration of Pentose in the Urine.*

2. The noteworthy features in this case of cerebrospinal lues was the appearance of tabetic symptoms, specially gastric crises and ataxia. The explanation of this was found at autopsy in degeneration of the posterior columns in the cervical and lumbar regions.

3. This article is a discussion of the status of the different varieties of streptococcus, of which the author recognizes with Schottmüller the following four varieties: S. longus, S. erysipel., S. mitior, S. viridans, S. mucosus, and S. lanceolatus (pneumococcus). These may be certainly differentiated by the use of Schottmüller's blood-agar and of litmus-nutrose-agar (Drigalski's medium). In blood-agar the S. longus shows a hemolytic areola, the mucosus gives an abundant slimy growth, while the S. lanceolatus and S. mitior both show green colonies. The latter two are distinguished by the use of Drigalski's medium, which is turned from blue to red by the S. mitior, but is unchanged by S. lanceolatus. The mucosus is not merely a variety of the pneumococcus, but a distinct species, for it retains its cultural characteristics and never changes so as to resemble the pneumococcus. The failures of some authors with these media are ascribed partly to the use of old cultures, partly to improperly prepared media.

5. The transplantation of goiters from man to animals hitherto has met with little success. Pfeiffer, however, has found transplanted bits of thyroid apparently functioning 127 days after operation. His method was to transplant small pieces of thyroid *immediately* on removal from the human subject into the spleen of dogs or goats. One feature of Graves's disease, tachycardia, was constantly present in all cases. It was greater, however, when the goiter of Graves's disease was used for transplantation, than with simple goiters. [W. T.]

1. *FRAENKEL, C. *Investigations on the Spirillum of European Relapsing Fever.*
2. *LASSAR, O. *Atoxyl in the Treatment of Syphilis.*
3. DETERMANN. *The Influence of Cold and Heat on the Viscosity of the Blood.* (Continued article.)
4. BING, H. J. *An Apparatus to Measure Blood Pressure.*
5. STILLMARK, H. *A New Sphygmomanometer.*

1. This article deals with the experimental inoculation of mice, rats and apes with specimens of the African and Russian varieties of the spirillum of relapsing fever. Fraenkel found that immunization against the one variety did not protect against inoculation with another variety, and that the serum of immunized animals used in the Pfeiffer experiment or hanging drop destroyed only that variety of spirillum which had been used for inoculation.

2. The destructive action of atoxyl on the trypanosomes of sleeping sickness suggested to Lassar, the well-known Berlin dermatologist, the use of this drug in syphilis. His results were disappointing at first, owing to too small dosage, but when he increased the dose to .5 gm. (7½ gr.) three times a week, he obtained surprising success. The syphilitic lesions, whether chancre or gumma, or secondary eruption, disappeared with great rapidity. He emphasizes the fact that close watching of the patient is necessary, owing to the possible poisonous effects of the drug. The future must decide how permanent the results with atoxyl are, and in what cases its use is indicated. [W. T.]

No. 23. JUNE 10, 1906.

1. *SCHIEK, B. *The Treatment of Scarlet Fever.*
2. HAALAND, M. *Observations on Natural Resistance to Tumor Growth in Mice.*
3. LAVUEUR, A. *Artificial Radium Baths.*
4. *LOHNSTEIN, H. *A Piece of Wax Removed from the Bladder by Solution in Benzine.*
5. POSNER, C. *An Interesting Case of Suprapubic Prostatectomy.*
6. HANSEMANN. *Remarks on Cancer of the Skin.*
7. *DETERMANN. *The Influence of Cold and Heat on the Viscosity of the Blood.* (Concluded.)

1. To avoid the infection of the home on the return of scarlet fever patients from the hospital, Schiek has adopted the following plan, with good results: the patients in the hospital are divided into three classes, those in the early, middle and convalescent periods. These are isolated from one another and a patient passing from one division to another is bathed and receives a change of clothing. By this means the danger that a child may be a carrier of the disease is reduced to a minimum. Uncomplicated cases are discarded at the end of six weeks with the advice that they be sent for two weeks to the house of relatives who have no children. The treatment consists chiefly in rest in bed, and a diet without meat, with cardiac stimulants freely used where indicated. Moser's serum has given excellent results. (This is anti-streptococcus serum made by using streptococci from the heart's blood of scarlatina patients for the injections of horses without intermediate passage through animals.) It must be given in the first few days to be of benefit, and so used, in the dose of 200 cc. subcutaneously, apparently aborts the disease. It does not, however, avert heart and kidney complications.

4. Lohnstein in a case of persistent hemoturia with cystitis, found as the cause a piece of wax in the bladder. With the cystoscope it could be seen floating on the surface of the water in the bladder. A few injections of benzine dissolved this foreign body without unpleasant symptoms.

7. An interesting contribution on the viscosity of the blood is made by Determann. He finds that after cold baths the viscosity is always considerably increased, while warm baths have the opposite effect. The electric light bath, however, increases the viscosity, perhaps owing to the possibility of evaporation of the sweat, which is absent in the warm bath. The blood pressure, red count, hemoglobin and specific gravity usually, but not always, showed parallel change. Artificial venous congestion caused a considerable increase in viscosity, due no doubt to the increased CO_2 content. [W. T.]

The Action of the Blood Serum of Nephritics upon the Frog's Eye, Resembling the Action of Adrenalin. Schur and Wiesel (*Wien. Med. Woch., No.* 23) found that serum obtained from patients suffering from chronic nephritis, even when diluted 20 times, caused marked dilatation of the pupil of the excised frog's eye, while serum from control individuals, healthy or otherwise diseased, never caused similar action. Apparently the mydriatic action of the nephritic serum is due to a functional increase in the "chromaffine tissue" of the suprarenal glands. This tissue is found constantly increased in chronic nephritis, especially with hypertrophy of left ventricle and high blood pressure. [L. G. M.]

Correspondence.

LETTER FROM FRANCE.

[*From our Special Correspondent.*]

Taking One's Own Remedies.

The Pyrenees, Aug. 15, 1907.

Mr. Editor: It is an excellent practice for physicians to taste their own medicines. Old Professor Guyon used to prescribe for his cases of genito-urinary tuberculosis a strong solution (4%) of creasote in cod liver oil. Curiosity led me one day to taste this mixture, and from that time to this I have never ventured to give creasote in that way; it is simply horrible, and would require a stomach of boiler-iron to stand for any length of time.

After I became a physician I formed the habit of tasting the preparations I prescribed, "to see whether it is right"; in reality, to learn what they were like. This custom served a twofold purpose: it familiarized me with all sorts of things of which I should have been cognizant but was profoundly ignorant, and it enabled me at a pinch to be very dogmatic. When recalcitrant patients complained that their medicine was nasty I was able to reply very sharply that such was not the case, "I have taken it myself," — an unanswerable retort.

As regards the first point,— the faculty at which I studied, a very ancient and renowned institution, had so organized its curriculum that the graduate of a five years course, that required an A.B. degree for entrance, was altogether unfamiliar with the appearance of pharmaceutical preparations and had never made a pill, powder or potion in his life, although he had given up an entire year to zoölogy, botany, physics and chemistry. When, then, as a young physician, I first began to prescribe, it was a constant source of interest, and often a surprise to me to behold the aspects of the products of my pen; and I passed through a number of those "regrettable incidents," which I dare say other physicians experienced too in their early days, when things didn't quite materialize as it had been hoped they would. I have a very vivid recollection of one patient bringing me a bottle in which phenacetin crystals were gayly bobbing up and down on the surface, when they ought to have been dissolved!

My aspirations for summer vacations are generally of a lofty nature; but this year I have had to accompany a relative to a spa for a course of treatment. So that I, who for years have been in the habit of distributing people to cures around Europe, have this time been obliged to take up again my former practice of trying my own remedies. However, though not a very exhilarating performance, it has not been without its peculiar interest.

This cure lies in the Pyrenees, the mountain-chain running from the Mediterranean to the Bay of Biscay, and forming the dividing barrier between France and Spain. Our particular spot is in the western portion of this range, where it runs down to the ocean, with Biarritz, the fashionable French watering-place, on the one hand, and San Sebastian, the summer resort of the Spanish royal family, on the other.

And here I desire to open an extra-medical parenthesis. The genial editor is probably away on his summer vacation, and I am counting on the "Sub" being short of copy, to let it go through.

The reason I gave the geographical details above is that philologically this western end of the Pyrenees is one of the most interesting regions in Europe, as it is inhabited by the remnants of a very old and remarkable race, the Basques. When at the dawn of history the Kelts issued from Asia and swept across the central and western portions of the continent they found them already occupied by a people whom the Romans called Iberians, but who speak of themselves as Euskarians. The present Basques, a few hundred thousand only, are the sole survivors of this once mighty race. In a similar way the Slaves and Teutons, who came after the Kelts, found in the north a people whom they pushed before them, and whose only representatives to-day are the Tshudic tribes, Finns, Lapps, etc., that lie along the Arctic coast.

These two peoples, then, are the oldest in Europe. Now when philologists came to look into the question they perceived that whereas the languages of Europe belong to the Indo-European family, that of the Basques and Tshuds cannot be connected with it in any way. These races were in possession of Europe when our forefathers arrived there; but whence they came or to whom they belong, no one has the least idea.

When the Basques woke up to the fact of their uncertain origin and great antiquity, their flesh became proud and their minds imagined a vain thing. Their language was the oldest in Europe and could not be connected with any other. The explanation was self-evident: it could only be that of the Père Éternel in person. And having laid claims to this parentage they stick to it and are to-day convinced that the tongue they speak and which no one can understand is the same as that spoken in Heaven! It is on account of this interesting point that I have thought it allowable to make this digression; since to rub elbows freely with people speaking the language of Heaven, and to see it in print and on the corners of the streets, is not given to ordinary mortals every day.

At San Sebastian I went into a shop to buy a Basque paper. The good woman looked at me dubiously, and remarked, as she handed it over: "*Si el Señor no entiende el Basquense,*" — the paper is not likely to be of much use. And she was about right; for a more hopeless looking lot of print I never saw. Judge for yourself: here is a paragraph taken at random:

"*Gizon onen, aitatu diran lanak, ikaragarrizkuak izandu ziran. Eraso ziyon bakarr bakarrik, Euzkadiren esati indarsubari ta onekin batubak zeuden euzkotarr zitalari. Atari ta etzeko jaun eta jabe izanik, kutizi kemen aulgarriyari begiratu gabe, denari jazarra bildurrgarriyan, ekin ziyon. Nai etzuben izan neurtu ta ez zenbatu oben aunditasuna.*"

Now I have a bowing acquaintance with the principal Latin, Teutonic and Scandinavian (though not Slave) languages; but there is not one syllable in that paragraph that I can make out, — and I may say the same for the rest of the paper. So there you have an illustration of what the Boston *Transcript* will look like when you reach the Elysian Fields; and you can now realize what is in prospect for any one intending to move on and settle in that district. Proper names run on this order: M. Borthagarayenia is a real estate agent in Cambo; Itxasson is a railway station; and Mlle. Ichuribéhère makes garments for the adornment of her sex.

The language is said to be *extremely* difficult to acquire, and to resemble Japanese in certain particulars. The people themselves relate that the Devil came and lived

among them once for seven years to try to learn Basque, but finally had to abandon the attempt. Here, however, there appears to be some misunderstanding. We have authority, the Scriptures, Dante, Milton, for believing that the Devil was once himself an Angel in Heaven, from which he was ejected on account of political troubles. The Euskara was consequently his mother tongue. If then at a later period he found himself entirely ignorant of it, this must be the earliest recorded case of retrograde amnesia.

I was moved to hear the true ring of this venerable speech, so I went to mass. This is the best way to judge what a language sounds like when you are first in a strange land. I once tried it on in Holland, forgetting the reputation of its inhabitants for "slimness," and had to sit out a Reformed Church service of *nearly two hours*, and listen to an endless sermon in two innings on Barabbas. The sacristan had slipped around and locked the doors!

I am happy to say that the fat curé who discoursed to the Basques that day — women below in the body of the church and men in galleries upstairs behind — was more of a Christian than his gloomy confrère in Holland; for his doors were very wide open, and we men strolled in and out and smoked between times. To listen to the language is nothing like as angular at it looks; in fact, its sound is quite pleasant, with no one peculiarity striking you disagreeably, as is often the case with a language you do not understand. I have now written to this curé for a small grammar; it is just as well to get the thing under way, if the language has got to be learned; though I fear that in these uncertain times my chances of coming any nearer things celestial than my brief sojourn among the Basques are not very great.

But to return now to medical matters, from which we have drifted pretty far.

In this Basque region I came across something distinctly out of the ordinary over here, — a really intelligent public railway W. C. Travellers in Europe have noticed the inexpressibly filthy conditions that usually prevail in such places among the Latin peoples, and since we are among medical men I may mention as an instance a W. C. I once saw in a good hotel in Italy, where the white window curtains, which hung down low by the seat, had been used by several persons for purposes where most people employ medicated paper. If I had not seen this myself I am afraid I should never have believed the story.

The Basque arrangement consists in a tile room whose floor slants in one direction, and at the further end of which is a depression pierced with a hole on whose either side is a small pedestal for the feet. There is a flushing apparatus of considerable force, and the entire room can be swept with a hose. Nothing more suitable from the point of view of cleanliness can be imagined, and as regards hygiene the system presents the advantage of the natural squatting posture which, in case you have never thought of this point, is a factor of no little importance in intestinal exoneration. There seems little doubt but that among the reasons for the great prevalence of constipation at the present day is the defective attitude in which the body is placed in the modern luxurious W. C. The squatting attitude of the primitives behind the nearest bush, with the great pressure brought to bear on the intestines by the mass of the thighs, was far preferable. Try the plan on a few constipated patients, and observe for yourselves.

The waters of our spa are pleasantly warm, alkaline and mildly sulphurous, the kind that are habitually spoken of as rotten eggs. This is, however, a gross libel. They are not at all disagreeable, even to drink; and employed in the form of spray, gargle or inhalation their sedative and modifying effect on chronic irritation of the mucous membranes is unmistakable.

This resort is frequented mainly by persons obliged to overtax their voice professionally: preachers, singers, lawyers, etc., but first and foremost among the clientèle is the curé, who is here in shoals, — half the curés of France and Navarre. I never saw so many curés, mostly elderly men worn out in their calling. What can there be in the mass that tears their throats to pieces in this fashion? Some of them have no voice left at all. Old Germain Sée used to be very caustic in speaking of this spa, to which, he observed, the curés went to meet the cocottes, all of them for the purpose of treating their mucous membranes!

But as I looked at these curés a thought occurred to me. To reach the spa they *all* have to pass through Lourdes, only two hours distant, and supposed, I believe, to be the holiest spot of pilgrimage in the Catholic world. The question then that at once crops up in the mind of the ungodly is this: Why do these curés come to be treated here, where they have to stay three weeks, instead of stopping off and being cured instantaneously at Bernadette Sonbirous' grotto? Can it be that, like other "preachers" who could be named, they are not given to taking their own remedies?

Seekers after the humorous should come and see this gargling establishment. The treatment is done in public, in long rows of little stalls, fifty on one side of the hall, and as many on the other. Taking your stand in the center aisle you see the patients all in profile. It is not easy to describe the *coup d'oeil;* but those of you who have farms can get an idea of it by going out and watching the chickens drink: the prolonged dip of the beak in the water followed by the stretch of the neck aloft with the idiotic look of ecstasy in the eye. That is about the picture.

It is surprising to observe the variety of ways in which the human being can gargle in public. There is the self-conscious man. He takes a small sip, gargles the roof of his mouth a moment, sends half of it down over his shirt front, and then looks in horror to the right and left to see if any one observed what he had done. Then there is the short-necked fat Monsieur with the apoplectic face. His efforts are quite alarming; his tint becomes purple, his eyes project from their sockets, and in the early days I used to feel for a lancet and prepare for phlebotomy. It never came off, however. Another manner is the gargle ecclesiastic. This was generally a very dignified affair. Some of the curés found the ordeal very trying, but resigned themselves to it with a humble spirit. You could see from the supplicating glances they cast on high that they were hoping that this mortification, too, would be reckoned to their credit. But the man who really rejoiced my soul was the old habitué, the patient with a previous season or two, who knew the trick. He comes in with an air of proprietorship, calls the girl by her first name, takes his water to his stall, pulls a small towel out of his pocket and ties it around his neck, and then with one hand on the side of his stall he throws himself back to arm's length and gargles with a conviction and uproar that can be heard for rods away. He was a daisy.

The fact is that it is not an easy matter to gargle in public, and that it requires some little practice to detach yourself from your surroundings and become unconcerned. The women seem to succeed better than the men. One little woman in gray that I used to watch was a wonder. She could gargle much longer at a time than any one else, and I came to the conclusion that she must possess in her interior some pneumatic apparatus on the order of the fish's swimming bladder.

One or two other points about this region may prove of interest. It is a land where the poppies are *yellow*. Now fancy that! This seems to upset the appointed order of things. In all well regulated countries with which I am familiar the wheat is sprinkled with poppies scarlet and cornflowers blue; and the puffs of wind as they pass along ruffle the surface of the field slightly and make it look like moiré silk. But what becomes of your landscape if the poppies are yellow!

Again, the peasants here have the loveliest mountain dogs, about the build of the Newfoundland but lighter, with white coats and the pointed head of the bear. Now it is a curious fact that the Pyrenees were once famous for their bears. These dogs are simply delightful, and the best natured beasts in the world in spite of their size. I saw one walk up to where its family baby was sitting on the floor and proceed to carefully lick its face and head indiscriminately with its great red tongue. The baby didn't seem to mind; merely tried to ward off the tongue with its arms.

But I see that I must close, although there are many things to relate about this beautiful Basque region. The present is, as I said, a vacation letter; when I return to Paris I shall have some recent medical developments to report.

"Spectator."

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED AUGUST 14, 1907.

GEDDINGS, H. D., assistant surgeon-general. Directed to proceed to Ellis Island, N. Y., for special temporary duty, upon completion of which to rejoin his station in Washington, D. C.

COFER, L. E., passed assistant surgeon. Granted leave of absence for 1 month. August 13, 1907.

GRUBBS, S. B., passed assistant surgeon. Granted leave of absence for 1 day, August 11, 1107. August 10, 1907.

FRANCIS, EDWARD, passed assistant surgeon. Directed to proceed to Mobile, Ala., for special temporary duty, upon completion of which to rejoin his station at Mobile Quarantine Station. August 9, 1907.

COLLINS, G. L., assistant surgeon. Granted leave of absence for 1 day, August 16, 1907. August 14, 1907.

OLSEN, E. T., assistant surgeon. Granted leave of absence for 1 month and 28 days from August 18, 1907.

MILLER, W. W., assistant surgeon. Relieved from duty at Ellis Island, N. Y., and directed to report at the Bureau in Washington for temporary assignment in the Hygienic Laboratory, August 9, 1907.

GIBSON, L. P., acting assistant surgeon. Granted leave of absence for 8 days from August 8, 1907.

GUSTETTER, A. L., acting assistant surgeon. Granted leave of absence for 30 days from September 1, 1907. August 6, 1907.

HUNTER, S. B., acting assistant surgeon. Granted leave of absence for 6 days from August 7, 1907. August 10, 1907.

MCGINNIS, R. H., acting assistant surgeon. Granted leave of absence for 30 days from September 1, 1907. August 8, 1907.

NUTE, A. J., acting assistant surgeon. Granted leave of absence for 20 days from August 20, 1907.

RODMAN, J. C., acting assistant surgeon. Granted leave of absence for 3 days from August 8, 1907. August 10, 1907.

SAFFORD, M. V., acting assistant surgeon. Granted leave of absence for 4 days from July 15, 1907, on account of sickness. August 8, 1907.

SAFFORD, M. V., acting assistant surgeon. Granted leave of absence for 4 days, from August 8, 1907, under paragraph 210, Service regulations.

SIMONSON, G. T., acting assistant surgeon. Granted leave of absence for 10 days from August 5, 1907. August 7, 1907.

WALKLEY, W. S., acting assistant surgeon. Granted leave of absence for 6 days from August 18, 1907. August 10, 1907.

GOODMAN, F. S., pharmacist. Granted leave of absence for 30 days from July 5, 1907, on account of sickness. August 8, 1907.

GOODMAN, F. S., pharmacist. Granted leave of absence for 28 days from August 5, 1907. August 6, 1907.

TROXLER, R. F., pharmacist. Granted leave of absence for 11 days from August 19, 1907. August 6, 1907.

ELDREDGE, M. B., pharmacist. Granted leave of absence for 23 days from September 3, 1907.

PROMOTIONS.

ASSISTANT SURGEON A. M. STIMSON commissioned as passed assistant surgeon, to rank as such from July 27, 1907. August 5, 1907.

ASSISTANT SURGEON W. C. RUCKER commissioned as passed assistant surgeon, to rank as such from July 27, 1907. August 5, 1907.

ASSISTANT SURGEON W. K. WARD commissioned as passed assistant surgeon, to rank as such from July 27, 1907. August 5, 1907.

ASSISTANT SURGEON J. W. TRASK commissioned as passed assistant surgeon, to rank as such from August 16, 1907. August 5, 1907.

APPOINTMENTS.

DR. CHARLES W. CHAPIN commissioned as assistant surgeon in the Public Health and Marine-Hospital Service, August 8, 1907.

DR. EDWARD R. MARSHALL commissioned as assistant surgeon in the Public Health and Marine-Hospital Service, August 8, 1907.

DR. RAYMOND B. SCOFIELD commissioned as assistant surgeon in the Public Health and Marine Hospital Service, August 8, 1907.

DR. EMIL KRULISH commissioned as assistant surgeon in the Public Health and Marine-Hospital Service, August 8, 1907.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING AUGUST 24, 1907.

JAMES H. HOLLOWAY, passed assistant surgeon. Camp Columbia, Cuba, will proceed to Palmira, Province of Santa Clara, Cuba. for duty, relieving Assistant Surgeon William A. Angwin. (Orders issued by the Commanding General, Army of Cuban Pacification.)

M. W. BAKER, passed assistant surgeon. Detached from the naval hospital, Boston, Mass., and ordered to the naval hospital, New Fort Lyon, Col.

E. C. TAYLOR, passed assistant surgeon. Ordered to the naval hospital, New York, N. Y., for treatment.

SOCIETY NOTICES.

THE THIRTY-FIFTH ANNUAL MEETING OF THE AMERICAN PUBLIC HEALTH ASSOCIATION. — The thirty-fifth annual meeting of this association will be held at Atlantic City, N. J., from Sept. 30 to Oct. 4, 1907.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION. — The thirty-third annual meeting of the Mississippi Valley Medical Association will be held at Columbus, O., Oct. 8, 9, and 10, 1907, under the presidency of Dr. H. Horace Grant, of Louisville, Ky. The orator in Medicine will be Dr. Geo. F. Butler, of Chicago, Ill., and the orator in Surgery Dr. Frank D. Smythe, of Memphis, Tenn.

RECENT DEATHS.

CHARLES FOLLEN FOLSOM, M.D., M.M.S.S., of Boston, died in New York, Aug. 20, 1907, aged sixty-five years.

DR. HORACE G. LESLIE, of Amesbury, Mass., a widely known physician and citizen, died Aug. 23 at the age of sixty-five. He received his medical education at the University of Vermont and went to Amesbury in 1867, where he has since lived. He served during the Civil War as a surgeon. In 1891-2 he was a member of the State Legislature, and in general was known not only as a physician of capacity, but also as a public spirited citizen.

DR. SAMUEL BEYEA, a prominent physician of New Rochelle, Westchester County, N. Y., died on Aug. 18 at the Roosevelt Hospital, New York, after an operation for gallstones. He was in the forty-third year of his age and had practised in New Rochelle for the past fifteen years.

Address.

SOME GENERAL CONSIDERATIONS REGARDING TUMORS.*

BY W. T. COUNCILMAN, M.D.

When your society honored me by requesting me to give this address I thought it would not be amiss if I should try to give you some of the general views on the subject of tumors which have come to me through their study. In this study the clinical side of the subject has been considered only so far as it has a direct bearing on the pathological side, so I must be pardoned if I touch but lightly the clinical aspect.

The subject of tumors is of perennial interest for the clinician, the pathologist, the embryologist and the medical statistician. The enormous advance in medical knowledge in the past three decades, which has brought to light the essential nature of many of the infectious diseases and thereby given us the indications for their control, which has revolutionized surgery and made it probably the most important branch of medicine, has but lightly affected the subject of tumors. It is true our knowledge of modes of diagnosis and methods of treatment, of structure, of modes of growth, has been increased, and the application of that knowledge to clinical treatment has given brilliant results, but of the essential nature of tumors we know but little more than we did thirty or even sixty years ago.

A tumor is a new formation of tissue which is without function and which has the power of independent and unlimited growth. At some point in the body the cells begin to grow and produce a tissue which may be circumscribed and easily separated from the adjoining parts, or it may be so infiltrated and closely related with the healthy tissue that it cannot be separated as a distinct mass. The growth arises from the cells of the body, and the structure produced agrees more or less closely with the tissues of the normal body. In some cases there is more analogy with the embryonic than with the adult tissues. The tumor may be composed principally or entirely of cells just as are the embryonic tissues, or between the cells there may be a varying amount of intercellular substance. Considered in its widest relations the tumor is atypical, that is, it does not conform to the type of normal structure. In some cases the tumor may agree exactly with a corresponding tissue in the normal body; thus it may be impossible to distinguish by the most careful microscopic examination the tissue of a myoma of the uterus from the normal muscle of that organ, but the departure from the type is shown by the fact that the tumor forms a circumscribed nodular mass of muscle such as does not appear in the normal uterus.

The tumors are independent structures which live in the body as does a parasite, taking their nourishment from it, but the body as a whole has no influence on the tumor. The nutrition of a tumor is independent of the general nutrition of the body. In cases of general malnutrition all the tissues of the body are affected, some, of course, much more than others, but it is not an uncommon thing to find a rapidly growing tumor in an individual in whom the general nutrition is reduced to a very low degree. The cells of a tumor are independent of the laws governing the general nutrition.

A tumor is without function. No matter how closely its structure may agree with that of some normal structure, it never exerts a corresponding function. One of the most striking examples of this is seen in the lipoma which is composed of fatty tissue which both macroscopically and microscopically agrees with the structure of the normal fat. We know that the adipose tissue is a special form of tissue in which fat is deposited, serving as a nutritional storehouse and increased or diminished in the varying nutrition of the body. Notwithstanding that the lipoma agrees in its structure with the normal fat, it in no way serves the nutrition of the body. I have seen a large lipoma in an individual in the last stages of tuberculosis and in whom the normal fat was reduced to the very lowest degree. No matter how strikingly similar the structure of an adenoma may be to that of a normal gland its cells do not produce a corresponding secretion.

The growth of a tumor is independent of the laws governing the growth of normal tissues. We know that in the course of normal development each tissue is produced by a process of differentiation. Tissues which in their full development differ widely both in structure and function are formed from cells of like character. The individual organs and the body as a whole continue to grow until a size is reached which corresponds to the type of the species, when the general growth ceases or is limited to that sufficient to repair loss. The growth of all organs is interdependent; at any time in the period of growth the same relative degree of development and size will be found in the different organs. No organ develops independently of the others; the liver and kidney correspond in size with that of the individual. In certain organs the growth is continuous from the embryonic period to the completion of growth; in others, as in the genital glands, there is a long period of quiescence after the embryonic period, and growth does not actively begin until the onset of puberty. The life of certain tissues is passed quickly. The thymus, certainly an active organ during fetal and for a short post-fetal period, instead of continuing to grow with the rest of the tissues, early undergoes atrophy. All the lymphoid tissues reach their full development early and atrophy instead of continuing to grow with the other organs. Notwithstanding that growth ceases with full development or is limited to the very slight degree necessary to compensate for the wear entailed by function, a considerable energy of growth remains which in various ways can be excited to activity.

Certain tissues and certain organs have a power of regeneration or of reforming tissue which may

* An address delivered before the Maine Medical Association, June 13, 1907.

be destroyed to a very much greater degree than others. In general, the younger the individual the greater the power of regeneration of the tissues; a tadpole quickly regenerates the tail when this has been cut off, but the adult frog is incapable of regenerating a limb. The less highly differentiated a tissue the greater the power of regeneration; the slightly differentiated epithelium removed from the surface of the body is quickly replaced, but nerve ganglion cells once destroyed are never renewed again nor can such a complicated structure as a renal glomerulus be renewed. We must assume that there is some means of regulating normal growth. Whether growth is regulated by means of the production of an internal secretion, or whether the regulation is more of a physical nature and due to the mutual relations of pressure is unknown. Certain things show the possibility of the regulation of growth by chemical substances. The thyroid probably has some such influence but the most definite example of the influence of a chemical substance on growth is that of the internal secretion of the corpus luteum. It has been shown that the growth of the mammary gland which accompanies pregnancy may be produced in a non-pregnant animal by the injection of an extract of the corpus luteum. That growth may be stimulated by alteration of the normal relations of the tissues to one another is shown in the repair of injuries. The surest way to excite a tissue of proliferation is by the production of an injury. All repair of wounds is due to this power of growth. Growth thus started by an injury persists until the normal relations of tissue are again established, when it ceases. Growing tissue demands more blood and new blood vessels are formed in it, but hyperemia alone will not excite tissue to grow; the tissue regulates its blood supply.

As compared with the normal tissues the independent growth of a tumor is its most striking characteristic. It is lawless, unregulated, and has no relation whatever to the growth of the body as a whole nor to the growth of the different organs. The fetus developing in the uterus of the mother is no more independent in its growth than is the growth of a tumor. Each may be regarded as an independent parasite deriving only nutrition from the host. A tumor begins to grow by certain cells of the body multiplying rapidly and independently. The cells in their general features conform to the cell type of the species but they show an extraordinary degree of variation. The cells of a tumor derived from squamous epithelium have the general characteristics of this and those derived from cylindrical epithelium have the general characteristics of cylindrical epithelium. As a rule, from the microscopic examination of a tumor, we can tell from what sort of tissue it is derived. Cell growth and multiplication in a tumor take place as in the normal tissues but present many variations. In normal cell division complicated processes take place in the cells which render it possible for the new cells to have parts of all the contents of the old. In the division of tumor cells the process is much more irregular. New cells are formed which have but a part of the contents of the parent cell, and instead of the cell dividing into two equal parts a triple or fourfold division may take place. It still remains a mooted question whether the tumor, once having started, grows only from itself or whether adjoining tissues can take part in the growth and become a part of the tumor. Certainly, in most cases this does not take place but I have occasionally seen in tumors of the breast appearances which seemed to indicate that certain of the ducts and other structures of the gland which had become included in the infiltrating growth of the tumor were taking on the same sort of growth and forming a part of the tumor. In certain tumors derived from the skin epithelium I have seen similar appearances in the hair follicles and glands. It is very difficult in these cases to be certain that the apparently normal cells which seem to be changing into tumor cells are not really tumor cells which have replaced the normal cells.

We distinguish in general two forms of tumor growth. One, termed the expansive growth in which the tumor enlarges as from a single center, remains a coherent mass and pushes away the surrounding tissue. Often the connection with the surrounding tissue is so loose that no trouble is experienced in the enucleation. Such type of growth is seen in those tumors which contain considerable intercellular substance or in which the cells are woven together to form a compact mass. In the infiltrating mode of growth the cells penetrate into the spaces of the surrounding tissue and in their growth force themselves or are carried by the lymph streams even deeper into this tissue. In such a tumor it is impossible to determine the limits of the tumor by the naked eye examination. What appears to be normal tissue may contain numbers of actively growing tumor cells.

Tumors are always connected with the surrounding tissues by blood vessels, and usually by considerable amounts of connective tissue as well. The blood supply varies and depends upon the rapidity of growth of the tissue. Tumors like other tissues make demands upon the blood for their nutrition, and the more active the growth the more abundant is the blood supply. The vessels vary much from the normal and have not the characteristic division into arteries, capillaries and veins. Into a normal organ one or several arteries enter, break up into capillaries and these coalesce to form a system of veins. There is nothing similar in the vascular supply of tumors. From all sides vessels of different caliber and often of capillary structure enter into the tumor, divide and ramify in it without definite arrangement. This is understandable from the development of the tumor which does not take place in a definite arterial territory but only in a small part of one, and the existing vessels are utilized for nutrition and very greatly enlarged. New vessels are continually being formed to keep pace with the rapid growth, but these have

rather the character of the vessels formed in inflammatory tissue and are not differentiated into arteries and veins. Owing to this irregularity of vascular formation the circulation of a tumor is not so perfect as that of a normal part.
